to any great extent until a temperature of about 125° C. has been reached begins to distil. The distillation is continued until a temperature of about 180° C. is reached, when the fire is extinguished and the receiver with bromhydric acid detached. The retort and its contents are allowed to stand till cold, when a quantity of water equal to about one-third of the bulk of the contents is poured into the retort. Heat is then again applied and the distillation continued until the temperature in the retort has reached the same height as before. This second distillation serves to remove a portion of bromhydric acid which cannot be removed in the first distillation.

The phosphoric acid which forms the residue in the retort is a black syrupy liquid, which, however, after dilution with water, digestion with about half per cent of purified animal charcoal, and subsequent filtration through white filtering paper (best the brand known as "Chlorine Paper"), becomes perfectly colourless.

The black colour of the phosphoric acid is due to an organic impurity of the commercial Br. which, it is said, is derived from the luting of the stills, in the composition of which tar is used.

The bromhydric acid, which has distilled over, requires to be redistilled before it can be considered sufficiently pure for pharmaceutical purposes.

If the addition of Br is made to an acid, from which the arsenic has not been removed, the entire amount of arsenic will distil over with the bromhydric acid, while the phosphoric acid will be found free from arsenic.

## Obituary.

### WALTER WELDON, F.R.S.,

FORMERLY PRESIDENT OF THE SOCIETY OF  
CHEMICAL INDUSTRY.

WALTER WELDON was the eldest son of a manufacturer at Loughborough, and was born on the 31st October, 1832. After having employed himself for some years in his father's works, he came to London, in the year 1854, and applied himself to literary pursuits. Of the labours and struggles of the following six years there is little to record. That they were sufficiently arduous and anxious we may well believe from our knowing little about them. They brought him assuredly neither name nor fame; and a writer who, in six years, shall have acquired in no measurable degree a literary reputation, can scarcely be supposed to have discovered prosperity either. Moreover, before coming to London, he had married a young lady of his own age (he was in his twenty-second year), Miss Anne Cotton, of a Derbyshire family. This imprudence, however, was certainly the wisest thing he had yet done, or was perhaps ever to do. Of the sustenance derived in those early days of discouragement and difficulty from the courage, energy, and devotion of his wife, he ever loved to speak; and it is only due to her memory,—for she too has passed away,—here to record it. During this period, he associated himself with the shareholders in a newspaper, proposed to be issued at this time under the title of *The Dial*, incorporated subsequently with the *Morning Star*, an influential Liberal London newspaper

of that day. In furtherance of this project, he travelled through the provinces, making acquaintance with many of the country booksellers, who could not fail to be impressed by his energy, and frank and manly bearing. The connections thus established were soon to prove serviceable. He had, in his early years, experienced the need of some periodical, by which the scientific discoveries and movements of the day should be placed on record as they arose, in a popular form, and at a moderate price; and to the establishment of such a publication he now addressed himself. It was originally designed to be a monthly "Register" of all facts and occurrences relating to the progress of Science. But he perceived, or was advised, that a periodical addressed solely to persons interested in science, to be published at the low price needful to reach those for whose benefit he proposed it, was unlikely, in that day, to obtain adequate public support; and he therefore determined to associate with his records of scientific inventions and discoveries, a "register" also of the progress, from month to month, of Literature and Art. In order to give the country trade a personal interest in his project, he arranged that the publication should be issued by each bookseller in the country subscribing for a sufficient number of copies, in *his own name*. It was to be published monthly, and the price was sixpence. On the 1st August, 1860, appeared, in London, the first number of *Weldon's Register of Facts and Occurrences in Literature, Science, and Art*. Among some of the early papers in it, may be noticed one on Mr. Darwin's then recently published work on the "Origin of Species," written, I believe, by Mr. John Marshall. It was followed by others on "Building Stones, why they Decay;" "Recent Elementary Books on Geology;" "Spectrum Analysis;" "Philosophy of Earthquakes;" "The Coal and Guano Dyes," etc., etc. Among the contributors of the more purely literary and artistic papers were Mr. Sala, Mr. Edmund Yates, Mr. Tegetmeier, Mr. Hollingshead, Mr. W. M. Rossetti, Mr. J. Hain Friswell, Mr. Percy Greg, and others who have since become more or less widely known by their writings.

The *Register* was continued for some three years, but it may be doubted whether, at any time, it secured commercial success. The price at which it was issued involved the necessity for a very large sale, and this probably it never attained. Finally, and fortunately for the world, it had to be abandoned.

Mr. Weldon then directed his attention, by what special inducements, at the moment, we possess no sufficient knowledge, to the subject of industrial chemistry. Brought up in the tenets of the school of Swedenborg, to which he was ever deeply attached, he had made the acquaintance of Mr. C. T. Hook, the well-known paper manufacturer of Snodland, near Rochester, who was also a Swedenborgian, and this may possibly have led him to direct his attention to the particular branch of industrial science to which, by "cheapening every sheet of paper in the world,"—to adopt the words in regard to his work of the eminent French chemist Dumas,—he was to be indebted for his fame as a discoverer and a benefactor of his race.

Arriving now at the commencement of Mr. Weldon's career as a technological as well as a scientific chemist, we find and are struck with the fact that in this career are displayed the marks of true inborn genius, genius of a kind peculiarly British, and which rose, as with Watt, Stephenson, and others, casting aside impediments and difficulties, to ordinary men insurmountable.

It has been said that genius only amounts to an immense capacity for hard work. No doubt, such a capacity must be present, and must be exerted to produce brilliant effects, but we believe that besides this, there are the special gift of an inspired soul, a fixed and ever-burning desire drawing towards that which is great or good, together with that of a clear mental vision, stimulating and calling into play the capacity for work which is given to every man, according to his physical condition.

Mr. Weldon, as we have seen, was not instructed, still less experienced, as a chemist, but rather as a writer and an editor of works of general literature. The time about which the *Weldon's Journal* was abandoned was the year 1863, and the nearest date to this at which any particulars are to hand relating to the transition period of his career, as it may be termed, is 1865.

In 1863, having reached what once appeared to him in a certain sense the goal of his modest aspirations and hopes, Weldon found, instead of pecuniary reward, pecuniary loss—but, he found besides, a new region with an apparently limitless horizon, for him almost without landmarks, and the paths of which when followed up gradually seemed to become mere tracks, these soon melting away to blend with the great unknown expanse before him. But, possessing genius, the new land, with what little he knew of it, presented irresistible fascination, and being further impelled by necessity, besides having the indomitable perseverance and courage of the true Briton, he explored the land, found his right path, and discovered eventually too that he had only missed his first goal to attain a higher: how much higher we are now to record.

Let us see how this is borne out. From some notes with which we have been favoured by Mr. John Spiller, we gather that in 1865 Walter Weldon was already engaged with the invention of certain chemical processes. On Monday, September 18, 1865, according to appointment, Mr. Spiller met Mr. Weldon with his friend Mr. Greg, for the purpose of hearing the details of these processes described in confidence, and of giving an opinion. The proposals referred to the manufacture of magnesium and aluminium by two new processes. For the first, Weldon proposed to heat together magnesia and iodide of sodium, whereby he obtained a double iodide, which was said to be easily decomposed by sodium, or even by lead, with production of metallic magnesium. The second suggestion was to flux cryolite with chloride of calcium, and to use this mixture as a source of aluminium, instead of the more expensive chloride demanded by Deville's process.

Col. Gamble, who next interested himself in Mr. Weldon's experiments, and at whose works in St. Helens the experiments leading to the foundation of the Weldon Process were actually wrought out and the process itself was adopted,

has kindly supplied the following particulars in a letter:—"I cannot now remember," writes Col. Gamble, "by whose intervention I first knew Mr. Weldon, but our first meeting was in London in the latter part of 1866, when he repeated before me in my bedroom at the Tavistock Hotel, some experiments which he had made on the production of soda by the decomposition of common salt by hydrofluoric acid, and which I believe he had patented. My opinion of this process being unfavourable to its success, in the first instance on account of the impracticability of obtaining apparatus capable of resisting the action of the materials, he called my attention to some experiments he had made on the oxidation of protoxide of manganese by blowing air through it whilst suspended in water, by which he thought he had obtained a peroxide.

"At this time, he appears to have been totally unacquainted with quantitative chemical analysis, or the results to be obtained from it, and I informed him that his process had been worked on a large scale by Mr. Gossage at Stoke Prior in Worcestershire several years before, with the result of only obtaining a very light sesquioxide, which it was found was a very unsatisfactory material to work with in obtaining chlorine, and the process was therefore abandoned.

"I had a considerable number of experiments made at my laboratory in St. Helens, extending over a long period, most of the time under Mr. Weldon's supervision, when it was discovered that the presence of chloride of calcium and an excess of lime along with the protoxide to be oxidised, was necessary for the production of a higher oxide than sesquioxide. But our experiments did not lead us to what appeared to me a workable process. Sometime in 1867 Mr. Weldon discovered the magnesia manganese process, which he patented, and the experiments upon it, conducted on a manufacturing scale, delayed our progress with the lime process, which we did not get to work for making bleaching powder till sometime in 1868. In the meantime some experiments had been conducted by Mr. Weldon on the Tyne (I believe at the Walker Alkali Works), so it was not until sometime in 1869 that we worked the process on a manufacturing scale."

The extracts from Mr. Spiller's notes and Col. Gamble's letter may be usefully supplemented by the following, written by Mr. Weldon himself, and taken from the *Newcastle Chronicle* of July 5th, 1884:—"The first experiment, other than laboratory experiments, with what is now known as 'The Weldon Process,' were made at Walker, in the demolished works of the Walker Chemical Company, about the year 1866. After having reached a certain point the experiments at Walker were abandoned for various reasons. They were soon afterwards resumed at the works of Messrs. J. C. Gamble & Sons, at St. Helens, Lancashire, and it was there that the process was finally worked out."

It will be seen from the extract from Colonel Gamble's letter how much knowledge, as well as experience in theoretical and applied chemistry, Mr. Weldon had yet to acquire in 1866. The writer has before him a letter dated March 8th, 1883, acknowledging the receipt of an address on the subject of instruction in applied chemistry, in which he (the writer) had unwittingly referred to Mr. Weldon as "a trained

chemist," in the ordinary sense of the term. The following is the extract of that letter bearing reference to the matter:—

"I have read with great interest your lecture," writes Mr. Weldon, "report of which you so kindly sent me recently, and I heartily agree with its general argument. But it was a mistake to quote me as an example of a 'trained chemist.' I never heard a chemical lecture in my life. Though few men were more intimately acquainted with the whole *literature* of chemistry, I had never entered a chemical laboratory, or seen a chemical experiment, when I patented, not Weldon's process as it is, but what *led* to it!"

This extract, coupled with the information given by Mr. Spiller and Col. Gamble, throws much light backwards, as it were, on the probable nature and direction of the toilsome reading and study which must have largely occupied nearly three years preceding 1865, and following the abandonment of the *Weldon's Journal* in 1863. It may be safely inferred that a large proportion, both of time and strength, was during this period devoted to the study of chemical literature.

If any man desire then to know what genius is, as well as what hard work may do, let him read first the extracts referring to 1865 and 1866, and secondly, let him read, if he had not the good fortune to hear, that Address delivered in 1884 at Newcastle-on-Tyne, at the close of Mr. Weldon's presidential year with the Society of Chemical Industry.

With regard to the discovery of the chemical reactions and their utilisation, which led to the great Weldon Process, we have a full description from Mr. Weldon's own pen in the last number of this Journal, page 525, as well as a foreshadowing of further problems for future working out, should life have been spared to him. Suffice it to say, that after many experiments with the object of recovering the manganese as peroxide, which had previously been lost as chloride in the liquors, run from the chlorine stills of the bleaching powder manufacturer, he at length succeeded in his design.

The manganese formerly lost was recovered to the extent of 90 to 95 per cent.; the price of bleaching powder was reduced by £6 per ton; its production was quadrupled, and something like £750,000 per annum were added to the national wealth. As M. Dumas, the great French chemist, observed in his address when presenting to him the gold medal of the Société d'Encouragement, "By Mr. Weldon's invention, every sheet of paper and every yard of calico has been cheapened throughout the world."

This was a notable achievement, and was recognised nowhere more cordially than in France. By the French Government Mr. Weldon was nominated Chevalier of the Legion of Honour, and he received, as we have said, from the Société d'Encouragement its great medal, conferred on only four other persons, Lesseps, Boussingault, Deville and Giffard. Nor did this great service to the cause of Industrial Chemistry pass unrecognised by the leaders of scientific thought in his own country, for on the 8th of June, 1882, Weldon was elected a Fellow of the Royal Society.

He was a man of prodigious energy and perseverance, coupled with knowledge of the

world and capacity for business; and to these qualities was largely due the rapid and successful adoption of his invention. He spared no pains and neglected no details. Nor was his attention limited to his own invention. He had made himself more or less familiar with all branches of chemical industry, and in the alkali trade was regarded as an expert whose judgment was of the highest value.

He was a leader in the formation of the Society of Chemical Industry, the welfare and progress of which lay very near his heart. As President of that Society he delivered, as has been already mentioned, an address at Newcastle-on-Tyne in 1884, which excited extraordinary interest. Granted the correctness of all the premises, as a piece of scientific literature this is a perfect model of lucid reasoning, besides possessing, for writing of such a kind, a strange fascination for the reader.

To his scientific attainments he united, as may indeed be now inferred, singular literary skill; and there was not perhaps another man in England who could make a difficult matter more plain to people of ordinary intelligence, and this without the least sacrifice of accuracy or evasion of detail.

Mr. Weldon's earnest devotion to official duties during his presidency of the Society of Chemical Industry in 1883-4, will probably never be forgotten by his colleagues, both of the Council and of the Publication Committee. But he went far beyond ordinary official duties in the self-sacrificing and generous attempt to attain to higher ideal standards set up within himself. It was sufficient for him that help was needed at some point, that someone was wanted, and that he had the ability to render the required assistance, not to justify merely, but to impel him to offer himself. Thus it came about that during his period of office as President, he sacrificed very largely both time and strength, as well as money, in the interests of the Society of Chemical Industry and its Journal. That these are no figures of speech merely, nothing is easier to prove. As one example among many: When abstracts of English patents were generally introduced into the Journal, and difficulty was at first found in getting these abstracts properly made, Mr. Weldon at once undertook the work himself, and for a considerable period the abstracts came in regularly, a considerable proportion of them in his own handwriting. In fact, all the unsigned abstracts appearing in the Journal about the first half of the year 1884, are his work. The following is an extract of a private letter received from him, by the writer, and dated March 1, 1884, with reference to the self-imposed task above referred to, the conscientious carrying out of which, to the very letter, will be sufficiently manifest, after a reference to the Journal and a perusal of some of these abstracts, which are models of their kind. "As regards myself," writes Mr. Weldon, towards the close of his presidential year, "the time the abstracts of patents occupy me is ruinous. Still, I shall not leave the Society in the lurch at any time, whether President or not."

Besides the vast labour and anxieties entailed by the writing, technological researches, etc., involved in the evolution and maintenance of the very numerous patents bearing his name, or taken out jointly with others, Mr. Weldon kept

fully abreast with the advance of the inorganic portion of pure chemical science; and he occasionally contributed papers, which always contained something of original thought, and were always a pleasure to hear or to read. At the meetings of the British Association in Montreal last year, he contributed a paper on the "Periodic Law," and quite recently he had published for private circulation a work "On the Ratios, one to another, of the Atomic Weights of the Elements," Chapter I. This Chapter I. is devoted to "The Glucinum Family."

The idea of the simplicity of matter and the existence of a common element, is a very old one, and one that has been fondly nurtured by physicists of all ages. Prout's hypothesis partakes of the same nature; its unit is, however, arbitrary and suggestive of hydrogen as that common element. Weldon, in this his last work, accepts the relations between the elements in the Newlands-Mendeléef series as expressive of a common typical structure; he then deduces from the atomic weights of the members of the series taken, a constant which admits of their expression in a relation to one another of a simple character. It is to be hoped that though deprived of his lucid reasoning, a continuation of this work may yet be possible, along the lines indicated in it.

Like so many in this strenuous generation, Mr. Weldon suffered from over-work. Never satisfied with what he had done, he entertained larger designs, labouring unremittingly for their development. Continually warned that the strain on his energies was excessive, he held on in weakness as in strength. For a long series of years he had attended the meetings of the British Association, and went to the recent gathering at Aberdeen, but only to discover that he was too unwell to take his accustomed share in the proceedings. To a friend meeting him as he was on the point of leaving town for Aberdeen, he said: "I am going to the British Association, though I am very unfit. I have never missed a year since my wife and I first attended the meetings, and I do not like to do so now; but it will be the last." He returned to his home, Rede Hall, Burstow, Surrey, on September 16th, and on the 18th wrote to a friend that he "had been ordered to do no work on pain of almost instant death," adding, with reference to some matters of urgency, "I shall do my best." Two days later his life struggle was over, terminating at the age of 53, of disease of the heart,—a career full of achievement, and with what seemed sure promise of yet greater success.

For the following notes on the personal qualities and characteristics of this distinguished man, as well as for those relating to his earlier and literary career, we are indebted to one of his oldest and most intimate friends, Mr. Alaric A. Watts:—

"I have not known," Mr. Watts writes, "any man in whom the intellectual and emotional elements in human nature were so harmoniously and happily married as in my friend. Each took its own place, and fulfilled its own special duties side by side, out of an abundant affluence of both; nor were their combined influences wanting. In him, as was justly remarked at his funeral by one of the friends of his later life,

Mr. Alexander Chance, 'Science never operated to chill the heart.' He was generous to a fault; there was indeed in his nature something princely. He loved to make happy and to serve; and the eminently practical character of his imagination enabled him instinctively to seize occasions for doing so which, with the best intentions, might not have occurred to a less gifted nature. With him, benevolence needed no culture.

"The quality in his nature which I have described as 'princely' entered into all his actions, and was a necessary concomitant of all his surroundings. A man of the simplest personal habits and desires, there was nevertheless in him an expansiveness which delighted to surround itself with what was beautiful and grandiose—a certain largeness which made space and dignified environments a necessity of his being. There was nothing in him in any respect small or narrow. He 'dwelt ever in large places.' His address and deportment to all persons was frank and cordial; gentle, and, when the occasion demanded it, instinct with a modest and gracious dignity that was extremely engaging. He possessed much tact and delicacy of feeling, associated ever with entire sincerity and truthfulness, and a firm and resolute will. He was endowed, in a remarkable degree, with that capacity for taking pains which a high authority assures us is the invariable accompaniment of true genius, if indeed it does not constitute it. No matter, either of business or otherwise, with him was so insignificant as to be dealt with otherwise than in the most complete and perfect way within his knowledge and power. A radical in the true and only real sense of the term, he penetrated ever to the root of things, and was thorough in whatsoever he set his hand to. Notwithstanding the arduous and incessant labours of his life, he found time, either in the early morning or in the watches of the night—which his persistent activity of brain rendered too frequent,—to keep himself fairly abreast of the miscellaneous literature of the day, supplying himself with whatever was of genuine excellence in all its branches. He was no patron of circulating libraries, caring little to read a book not worth buying. But his supreme delight was in his garden and pleasure grounds, in the construction and development of which he spent all that he could spare of his time, and possibly, sometimes, more than he could spare of his money.

"As a companion he was cheerful and genial, and eminently sympathetic—not insensible to the charms of light humour, but more instinctively attracted to what was pathetic and of noble sentiment. I cannot conceive the possibility of anything base or unseemly being uttered in his presence. Care had accompanied his march to fame, and sorrow with him was not lacking to temper the heats of prosperity. The loss of one of his sons, a bright and engaging young man, followed soon after by that of his wife, to whom he was tenderly attached, and for whose gratification to him prosperity was mainly valuable, affected with a tender melancholy the later years of his life. Moreover, during all his life he was more or less a sufferer physically. His nerves were too finely strung for much of the work he had to perform, and though in his later years of a robust and vigorous frame and aspect,—some who read these words may recall the terrors of the grip of his strenuous hand,—his

physical strength was not always answerable to the heavy demands made upon it by the energy of his will and his almost morbid sense of duty. He suffered at intervals from violent attacks of neuralgia or brow-ache; and the long journeys which he was compelled so frequently to take on the Continent and elsewhere on the affairs of his company and otherwise, were well calculated, by accelerating the action of the heart, to induce the disorder to which he was ultimately to succumb. His interest in the present and his hopes in the future were, however, happily kept alive by his elder son and the present representative of his family, Mr. W. F. R. Weldon, M.A., of St. John's College, Cambridge, and Lecturer on Invertebrate Morphology at that University, married, in 1883, to the eldest daughter of his friend, Mr. William Tebb, of Albert Road, Regent's Park.

"Those who take interest in such matters may care to know that, though perturbing his mind little with party politics, Mr. Weldon was a staunch adherent of Mr. Gladstone. In religious belief, he was a Christian of the Swedenborgian type. These latter views and sympathies led him early to take an interest in the phenomena of modern spiritualism, which he had carefully investigated and in which he believed.

"A short time before his death, the writer received a letter from him, with the concluding paragraph of which he may be allowed to terminate these imperfect notes. 'The last time,' he said, 'I walked in my garden with my dear wife, I noticed, early as it was, the leaves on a certain tree turning brown. We were of course thinking of Dante\*. I quoted to her these lines from verses of our poor friend Spencer Hall:—

"The Autumn days are come again,  
The hedges redden in the lane,  
The leaves are golden on the tree,  
And golden memories bloom in me."

\* His younger son, then recently deceased.  
† We had met first at this gentleman's house.

## London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

### Committee:

Sir F. A. Abel.	R. Messel.
H. E. Armstrong.	B. E. R. Newlands.
W. Lant Carpenter.	B. Redwood.
W. Crowder.	T. Royle.
C. Graham.	John Spiller.
S. Hall.	G. C. Trewhy.
A. K. Huntington.	J. Williams.

Local Sec. and Treasurer: T. Thos. Trier,  
Garden Wharf, Church Road, Battersea, S.W.

MEETINGS, SESSION\* 1885—86.—First Monday in each month (unless otherwise indicated).

### SPECIAL MEETING.

October 26.—Mr. Frederick Siemens, being in London, will attend the discussion of his Paper read at the last Annual Meeting, "On Heating Regenerative Gas Furnaces by Radiation from Flame, and on Producers to supply Gas specially Suitable for that purpose, and for the Recovery of By-Products."—(See Journal for July, 1885, pp. 41—39.)

## ORDINARY MEETINGS.

First Monday in the Month, at 5 p.m.

November 2.—Dr. C. R. A. Wright, F.R.S., and Mr. C. Thompson—"Notes on the Chemistry of Soap." Mr. V. H. Veley—"On the Lime Process for the Purification of Coal Gas."

December 7.—Dr. P. F. Frankland on "Some Aspects of Filtration and other Methods of Water Treatment." Dr. F. L. Teed—"Note on the action of Calcium Carbonate on Solution of Ammonium Chloride."

January 4, 1886.—Mr. G. E. Davis—"On the Enrichment of Coal Gas by certain Hydrocarbons." Mr. C. T. Kingzett—"Notes on Russian Turpentine."

February 1.—Mr. Gustav Bischof—"Notes on Dr. Koch's Water Test." Mr. J. W. Westmorland—"The Estimation and Valuation of Copper Ores and Products for Commercial Purposes."

March 1.—Mr. Boverton Redwood—"Researches on Viscosity."

April 5.—May 3.—Messrs. Macnab and Beckett—"The Treatment of Water for Technical Purposes."

June 7.—Dr. Mcymott Tidy—"Chemical Treatment of Sewage."

July.—Annual Meeting at Liverpool.  
Notices of papers and communications for the meetings to be sent to the Local Secretary.

## Manchester Section.

Chairman: Sir H. E. Roscoe.

Vice-Chairman: I. Levinstein.

### Committee:

R. F. Carpenter.	D. B. Hewitt.
C. Estcourt.	C. Schorlemmer.
H. Grimshaw.	Watson Smith.
B. W. Gerland.	L. Siebold.
Peter Hart.	Wm. Thomson.
T. Jackson.	D. Watson.

### Local Secretary:

J. Carter-Bell, Bankfield, The Cliff, Higher Broughton, Manchester.

MEETINGS, SESSION 1885—86.—First Tuesday in each Month, at 7 P.M.

November 3.—W. Thomson—"Indiarubber and its Decay." Dr. B. Gerland—"Potassium Antimony Oxalate." G. E. Davis—"The Valuation of Crude Naphthas of Commerce."

December 1.—A. H. Allen—"Further Notes on the Chemistry and Analytical Examination of Fixed Oils." Watson Smith—"The Violet Stains appearing on Sized Cotton Cloth" (*Experimentally Illustrated*).

Notices of papers and communications for the meetings to be sent to the Local Secretary.

## Journal and Patent Literature.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improvements in the Production of a Compressed Gaseous Compound, for use in Gas Motors and for other purposes, and in Apparatus therefor. Emil Capitaine and Oscar Brünler, Berlin. Eng. Pat. 7581, June 22, 1885.

A SUITABLE liquid hydrocarbon is forced into a strong closed vessel to which heat is applied. The vapours evolved are allowed to escape under great pressure to a properly constructed receiver, passing on their way through an injector-like apparatus whereby sufficient air for combustion is drawn in and mingled with the vapours. This gaseous mixture is ready for explosion in the cylinders of gas engines, and is to be so admitted that the fresh charge expels the spent gases from the cylinder.  
—A. R. D.

### II.—FUEL, GAS, AND LIGHT.

Improvements in the Manufacture of Gas. J. Quaglio. Chem. Zeit. 9, 959.

REFERRING to Fahnchjelm's invention, the author considers that an important step in the progress of the gas

industry would be realised, should the process prove to be successful. It is based on the use of water gas for illuminating purposes without carburetting, by raising threads or needles of magnesia to a white heat by the flame of the gas. In discussing the improvements in the manufacture of gas during the last ten years reference is made to the use of gaseous fuel for heating gas retorts. It is stated that formerly all the coke produced in gas making was used as fuel, whilst at the present time the average consumption is only about 33 per cent., the Munich gas-works using as little as 15.75 per cent. of the coke produced. The first attempts to apply regenerative furnaces for the heating of gas retorts were made in Germany by Oechelhäuser, general manager of the Dessau works. Of the many systems now in use in Germany and England the author refers to the following as being the principal ones: Siemens' system, the process invented by Schilling and Bunte, and the Hasse-Didier and Hasse-Vacherot systems. These furnaces are constructed on the principle of utilising the waste heat by passing it through a series of flues and thus heating the air necessary for promoting combustion. A further improvement is the construction of a mouth-piece for gas retorts invented by Morton, which requires no luting. Hasse, of Dresden, has improved the construction of hydraulic mains, the object being to prevent the stoppage of the pipes. His apparatus admits of the removal of the tar, whilst the retorts are at work, without loss of gas. In conclusion the author briefly refers to the use of Körtzing's injectors for exhausters, the scrubbers patented by Kirkham, the construction of gasometer according to Sütze's principle and other arrangements relating to gas-making.—D. B.

*Calorific Power of Coal-gas variously diluted.* A. Witz. Compt. Rend. 100, 440.

WHEN mixed with six volumes of air the calorific power is about 5200cal.; before passing through the scrubber and purifiers the same gas gave 5600cal. With 1.25 volumes of oxygen the calorific power was 5 per cent. higher, with 11 volumes of oxygen 4.6 per cent. lower, but with 10 volumes of air it was 2.5 per cent. higher than with six volumes.—S. Y.

*The Revivification of Hydrate of Lime after it has been used for the Purification of Gas.* John Reid, Birmingham. Eng. Pat. 1084, January 26, 1885.

THE lime after being removed from the purifiers is put on an open kiln or stove in a layer of from four to five inches thick, and occasionally turned over. At a temperature of from 120° to 150° F. the impurities are driven off in from two to three hours.—S. H.

*Improvements in Apparatus employed in the Treatment of Coal in order to obtain Coke and By-products therefrom.* Richard de Solderhoff, Merthyr-Tydvil. Eng. Pat. 11,967, June 3, 1885.

THE coking ovens are of a rectangular shape, and provided on the side, just by the spring of the arch, with openings leading into a conducting flue situated above the side-wall and running the full length of each oven. Each conducting flue communicates with the main collecting flue which is above, and runs the entire length of the whole set of ovens. From the collecting flue the gases pass through two flues situated in the side walls of each oven, one above the other, and then through flues underneath the ovens to the chimney. The air necessary for combustion is heated by passing through small flues grouped about the heating flues beneath the ovens, and then passes to another flue situated between the two heating flues in the side walls. This flue is perforated on the top in one half of its length, and on the bottom in the other half, so that a good distribution of the air is effected, and perfect combustion of the gases ensured. As an alternative arrangement the gases may be led from the conducting flues to suitable washers and scrubbers, returning thence to the collecting flue, and being burned as above described. When this is done it is proposed to pass the gases through a refrigerating condenser consisting of a tube fitted with a screw to lengthen the passage of the gas: the tube being placed in a tank within which cold water is constantly circulating. (Compare this Journal, iii. 510 and 511.)

—A. R. D.

*Improvements in and relating to Apparatus chiefly designed for Utilising the Waste Heat from Coke-Ovens, or other Furnaces for Evaporating, Calcining, and other purposes.* C. Kingsford, London. Eng. Pat. 2379, June 12, 1885.

ABOVE a coke-oven the inventor disposes a series of tray-shaped shelves so that the gases evolved in the coking may be burned and pass under and over each shelf in succession. Liquids are admitted to the topmost shelf in such quantity that as they flow downwards from shelf to shelf the evaporation is completed when they reach the bottom, where the residue is removed through a manhole.—A. R. D.

*Improvements in Apparatus for the Combustion of Liquid Fuel.* J. D. Bodwell, San Francisco. Eng. Pat. 7615, June 23, 1885.

THIS apparatus consists of a closed chamber provided with air inlets and with an opening in one of the sides near the top, for the escape of the products of combustion. The interior is fitted with a series of shelves, one below the other, sloping downwards from the sides, and reaching about two-thirds of the distance across the chambers. Oil is admitted to the topmost shelf and falls from shelf to shelf, burning during its passage, the shelves meanwhile presenting the appearance of sheets of flame. When it is intended to use this apparatus for heating water, pipes containing the water, preferably placed so as to allow of its circulation therein, are arranged suitably in the heating chamber.—A. R. D.

*Apparatus for Combustion of Liquid Fuel.* Jno. Imray, London. From H. de Bray and C. D. Rosetti, both of Cairo. Eng. Pat. 12,990, June 24, 1885.

THIS invention applied to an ordinary Cornish boiler may be described as follows: An oil-tank communicates

with a retort situated in the crown of the fire flue by a pipe in which is inserted an air or steam jet. From the retort a pipe leads the oil or gases to a receptacle on the fire bars, to which a supply of air under pressure is also admitted. From this receptacle several pipes provided with small holes run lengthwise in the flue. The gases issue from these holes and burn, heating the retort and also the boiler. The supply of oil to the retort is maintained by the air or steam-jet in the pipe leading from the oil-tank. The fire-bars are covered with some material which is a non-conductor, and excludes the air. A perforated pipe at the bridge of the flue supplies baryta, permanganate of potash or other oxidising agent, to effect the complete combustion of any imperfectly burned gases.—A. R. D.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*Removal and Utilisation of the Waste Acid of Petroleum and Tar Works.* Chem. Zeit. 9, 777.

OF the numerous methods employed for removing or utilising the waste acids obtained in the purification of crude petroleum and naphtha, the process based on the decomposition of the acid into sulphurous acid is said to be the most useful. In the absence of sulphuric acid works the sulphurous acid produced may be converted into sulphites or thiosulphates, or it may be treated in accordance with Roessler's process, which depends on the fact that an acid solution of copper sulphate, if treated with sulphurous acid in the presence of air, converts a corresponding quantity of the acid into sulphuric acid, which is then allowed to act on metallic copper. The sulphurous acid may be used also for the decomposition of solutions of sodium phenate; it is necessary, however, to remove all empyreumatic substances, which is best effected by passing the acid through a series of vessels, some of which contain water and others concentrated sulphuric acid. The solution of sodium sulphite produced by the decomposition of sodium phenate with sulphurous acid is causticised with calcium oxide, and the calcium sulphite thus formed used for the evolution of sulphurous acid, whilst the caustic liquor is employed for the extraction of fresh quantities of phenol.

—D. B.

*Direct Formation of Dibromothiophen from Coal-tar Benzene.* Vietor Meyer and Otto Stadler. Ber. 18, 1884.

THIOPHEN is so much more easily acted on by sulphuric acid than benzene, that a separation of the two bodies may be effected by means of this reagent, but the authors state that bromine gives still better results, the yield of bromo-derivative of thiophen being almost quantitative. A mixture of 500grm. of pure coal-tar benzene with 30grm. bromine was allowed to stand for several hours, being repeatedly shaken. Hydrobromic acid was copiously evolved and the liquid became almost colourless. It was washed with water and caustic soda, and the benzene distilled off from the water-bath. The residual dark-coloured oil was freed from bromine addition products by warming with alcoholic potash, and after addition of water it was hydrolysed. A light yellow oil separated from the distillate, and more was obtained by extraction with ether. The oil was dried with calcium chloride and distilled, and yielded 13grm. of almost pure dibromothiophen. Experiments on the large scale were carried out in the Höchst Dyeworks (formerly Meister, Lucius and Brining). By the action of 12kilos. of bromine on 200kilos. of benzene, 3·85kilos. of a heavy oil were obtained, and from 100grm. of this the authors obtained 31·7grm. dibromothiophen and 5grm. monobromothiophen. In a second experiment 1kilo. of crude oil yielded 360grm. of the pure dibromo compound.

—S. Y.

*On the Reduction of Nitrothiophen to Amidothiophen.* Otto Stadler. Ber. 18, 1490.

THIS reduction is attended with considerable difficulty, for by the use of ordinary reagents, such as tin and hydro-

chloric acid, stannous chloride and hydrochloric acid, ferrous sulphate and ammonia, ammonium sulphide, sodium amalgam, zinc dust and acetic acid, zinc dust and ammonia, hyposulphurous acid and so on, either no reaction takes place, or it is so violent that the thiophen molecule is destroyed with evolution of hydrogen sulphide. The author has succeeded in effecting the reduction by dissolving 1grm. mononitrothiophen in 50cc. of alcohol saturated with hydrogen chloride and adding gradually 2grm. granulated tin. The tin is completely dissolved, and a tin double salt of amidothiophen crystallises out, and may be obtained pure by washing with alcohol. The mother-liquor on evaporation yields more crystals, which are best purified by washing with ether. The double salt has the composition

The base was set free by adding the theoretical quantity of hydrogen potassium carbonate, in complete darkness. A clear yellow oil is thus obtained which rapidly becomes resinous even in the dark.—S. Y.

*On Chrysene.* E. Bamberger and J. Kranzfeld. Ber. 18, 1931.

ACCORDING to Graebe and Bungeger, who have obtained chrysene by synthesis from benzylnaphthylmethane, the constitution of this hydrocarbon may be thus expressed—

so that chrysene is a phenanthrene in which in the place of a phenylene group  $C_6H_4$ , the bivalent naphthalene complex  $C_{10}H_6$  occurs. The object of the present research was to confirm the formula for chrysene by analytical means. According to Liebermann, chrysquinone has the formula  $C_{18}H_{10}O_2$ . It contains two carbonyl groups in neighbouring positions thus:—

The correctness of this supposition is proved by the colour which chrysquinone exhibits when treated with potash, and is supported by the properties which characterise the following derivatives: Chrysoglycollic acid, chrysoketone, chrysfluorene alcohol, and chrysfluorene. The two carbonyl groups of chrysquinone exhibit reactions similar to those produced by phenanthrenequinone and retenequinone, the ortho-position of which has been conclusively determined. When chrysquinone is boiled with aqueous solutions of alkalis, chrysoglycollic acid is obtained in precisely the same manner as that in which under similar conditions diphenyleneglycollic acid is produced from phenanthrene. When chrysoglycollic acid is oxidised with potassium dichromate and sulphuric acid, chrysoketone is formed, which on reduction is converted into chrysfluorene alcohol and chrysfluorene; diphenyleneketone when treated under the same conditions yields fluorene alcohol and fluorene. The following is a comparison of the corresponding phenanthrene and chrysene-derivatives:—

$(C_{12}H_8) \begin{array}{c} < CO \\   \\ CO \end{array}$	$(C_{16}H_{10}) \begin{array}{c} < CO \\   \\ CO \end{array}$
Phenanthrenequinone.	Chrysquinone.
$(C_{12}H_8) > C(OH) \cdot COOH$	$(C_{16}H_{10}) > C(OH) \cdot COOH$
Diphenyleneglycollic acid.	Chrysoglycollic acid.
$(C_{12}H_8) > CO$	$(C_{16}H_{10}) > CO$
Diphenyleneketone.	Chrysoketone.
$(C_{12}H_8) > CH \cdot OH$	$(C_{16}H_{10}) > CH \cdot OH$
Fluorene alcohol.	Chrysfluorene alcohol.
$(C_{12}H_8) > CH_2$	$(C_{16}H_{10}) > CH_2$
Fluorene.	Chrysfluorene.

—D. B.

*Improvements in the Preparation of Mineral Oils for Woollen Manufacturing and other Purposes.* J. Swallow, Armley. Eng. Pat. 13,043, July 1, 1885.

To one ton of mineral oil is added 11lb. of borax and 17lb. of common soda in aqueous solution. The whole is agitated together, boiled for a few minutes, and then allowed to stand. The solution sinks to the bottom, and is separated in any convenient way. The oil is now again stirred up with a mixture of fullers earth and water, which is also afterwards allowed to settle out and separated. This process removes from the oil qualities that impair its usefulness for rag pulling, scribbling, and other operations in the woollen manufacture, and also materially diminishes its inflammability.—A. R. D.

*Purifying Paraffin Oils.* G. T. Beilby, Midcalder. Eng. Pat. 13,446, July 6, 1885.

AFTER the elimination of the basic and acid impurities with sulphuric acid and caustic soda in the usual way, the oil is mixed with a solution of caustic soda in ethyl or methyl alcohol and agitated in a vessel constructed to minimise the loss of alcohol by evaporation. The alcoholic solution of soda holding the impurities, sinks to the bottom on standing, and is separated by decantation. It is treated with open steam to drive off the alcohol. The supernatant oil in the mixing vessel retains a considerable quantity of alcohol, which must be removed by distillation.—A. R. D.

#### IV.—COLOURING MATTERS AND DYES.

*On a New Easy Method of Preparing Diamidotriphenylmethane.* G. Mazzara. Gazz. Chim. 15, 50.

THE method described by Fischer (*Ann.* 206, 147) is modified as follows:—A mixture of 45grm. benzaldehyde, 90grm. aniline and 100grm. fuming hydrochloric acid, is boiled for some hours in a flask with reversed condenser, the product is diluted with much water, filtered from resinous matter, and the triphenylmethane precipitated by caustic soda in the form of white flakes, which are washed with hot water and recrystallised from benzene. The crystals lose one molecule of benzene at 110°, and then melt at 139°.—S. Y.

*Liebermann's Phenol Dyes.* T. Lehmann and J. Petri. Chem. Centr. 16, 483—486.

By the action of nitrosyl-sulphonic acid on phenol two very similar colouring matters are obtained, one of which has been described by Liebermann, whilst little is known of the other. The authors prepared the first of these bodies according to Liebermann's directions and investigated its physical properties as well as those of one of its nitro-compounds. The dye is soluble in methyl, ethyl, and amyl alcohols, forming a yellow solution, and in ether, chloroform and acetone; it is less soluble in benzene and toluene, and insoluble in petroleum spirit. It dissolves in concentrated sulphuric acid, giving a dark blue-green colour. Such solutions of different strengths the authors examined spectroscopically, and found that they have characteristic absorption bands; their positions and variations with strength of solution are given in the paper. The dye is soluble in fuming nitric acid, forming a dark brown solution. If the liquid after filtering through glass wool be treated with water, the dye is precipitated as a dark green amorphous substance, which when dried at 100° C. has the following properties. It is soluble in ether giving a chlorophyll-green solution with a emerald fluorescence, which is very perceptible even in nearly colourless solutions; also in alcohol and acetone, giving a similarly coloured liquid, mineral acids dissolve it, giving a brown solution. The green colour is destroyed by alkalis and reproduced by acids. The original dye appears to undergo some change when heated with sulphuric acid to about 130° C., and a colouring matter is obtained which when well washed does not show two characteristic absorption bands, shown by the solution of the original dye, and it gives in alkaline solution a blue-violet colour instead of a blue green solution. The colouring matter so obtained resembles litmus in its behaviour, and the authors suggest it as an indicator. The prepara-

tion of this body is as follows:—5cc. phenol are mixed with 5cc. of concentrated sulphuric acid and the mixture is cooled, and then 20cc. of nitrosylsulphonic acid are introduced in small quantities at a time. The mixture is heated for some time on a water-bath at about 80° C., and is tested from time to time until the absorption band  $B_2^2C-D_1^2E$  due to the dye makes its appearance. On pouring the solution into 2 litres of cold water the dye separates as a dark-violet amorphous substance. It is filtered, washed and dried at 100° C. It is readily soluble in acetone, ether, and ethyl, methyl, and amyl alcohols, not so soluble in chloroform, soluble with difficulty in benzene and toluene, and insoluble in petroleum spirit. It is soluble in fuming hydrochloric acid to a yellow-red solution, Liebermann's dye when similarly treated giving a cherry-red colour. The spectroscopic properties of the dye are described in the paper. Fuming nitric acid dissolves it, and a dirty-brown body is obtained from this solution by the addition of water, which is soluble in ether, yielding a yellow-brown solution showing no fluorescence. It acts as a good indicator in alkalimetry, except in the case of ammonium salts.—S. R.

*Note on a New Class of Sulphonic Acids of the Aromatic Series.* Adolf Spiegel. Ber. 18, 1479—1482.

THE author has already shown that azo-colouring matters, formed by the union of a diazo-salt with a phenol or a base, yield with bisulphites, compounds which are soluble in water. If the azo-compound exist as a sulphonate, the reaction takes place readily in a warm aqueous solution. With the free azo-compounds, insoluble in water, the reaction may be brought about in alcoholic solution, for the alkaline bisulphites are soluble in alcohol. The bisulphite compounds obtained from red azo-bodies form yellow solutions, those from blue form red. They all crystallise well, and the crystals are dark and lustrous. They are stable with dilute acids, but decompose when heated or treated with alkalis into the colouring matter and the neutral sulphite. Textile fabrics may, therefore, be dyed by treatment with the aqueous solution of the bisulphite of the azo-body, and subsequent steaming or warming with alkali. The bisulphites are formed by the direct addition of the two bodies, and may be represented by the general formula—

The author has not settled yet whether the free acid is a stable or an unstable body, although he has noticed that, on treatment with concentrated acids, the solution becomes coloured before the original azo-colour is precipitated. In order to study the action of bisulphite on other azo-compounds, an alcoholic solution of azobenzene was treated with an alkaline bisulphite, when instead of direct union taking place, a shifting of the atoms occurred and a new sulphonate of benzidine, amidodiphenylsulphanic acid,  $\text{NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{C}_6\text{H}_4 \cdot \text{NH}(\text{SO}_2\text{H})$ , was formed. The azobenzene was soon dissolved when the mixture was warmed on the water-bath, but white cauliflower-like masses soon separated. After some hours, these were filtered, washed with alcohol and water, and dissolved in soda. By addition of an acid a glutinous mass of the new body was precipitated. It has acid properties, and forms crystalline alkali salts—e.g.,  $\text{C}_{12}\text{H}_{11}\text{N}_2\text{O}_2\text{S}$ . That the sulphonic group is combined with nitrogen was shown by the action of concentrated sulphuric acid, which yielded benzidine sulphate, from which the base was liberated and identified. The sulphanic acid evidently belongs to the group of bodies, the typical member of which was prepared by Fremy by the action of a nitrate on a sulphite (*Ann. Chem. Phys.* (3), 15, 408). When an aromatic nitroso-compound such as nitrosanaphthol is warmed with a bisulphite, the former is dissolved, and on addition of an acid, a yellow powder soluble in alkali is precipitated. It is reprecipitated from its alkaline solution by addition of an acid, and when heated with water to 150° yields naphthohydroquinone. Also some nitro-compounds, for instance nitrophenanthrenequinone, were acted on by bisulphite, and similar results obtained.—S. Y.

*Theory of the Formation of Rosaniline in the Nitrobenzene Process.* M. Lange. Ber. 18, 1918.

It is usually assumed that the nitrobenzene in supplying the oxygen required for the rosaniline formation is itself reduced to aniline and partly enters the rosaniline molecule. The author considers that this is not the case, but that the nitrobenzene loses its nitrogen and is completely reduced to benzene. 40grm. of a mixture of aniline and toluidine were half neutralised with HCl and heated with 20grm. of nitrobenzene and a small quantity of ferric-chloride or ammonium vanadate to 190°: besides rosaniline the melt contained phosphine, an induline-like body, and diphenylamine, and benzene occurred in the distillate. The same melt was obtained by replacing the nitrobenzene by chloronitrobenzene, no chlorinated rosaniline being formed. Exactly the same result was produced by the employment of nitraniline, dinitrobenzene, nitronaphthalene, etc., aniline being evolved and the hydrocarbon formed. If pure paratoluidine, half neutralised with HCl, was heated with nitrobenzene and ferric-chloride, hardly any rosaniline was obtained, whereas if the nitrobenzene were reduced to aniline during the process rosaniline must have been produced. If nitro-bodies containing methyl groups be used the reaction is more complicated, since the CH<sub>3</sub> groups appear to get oxidised off and form the nucleus of the rosaniline molecules. Thus if pure aniline (obtained by repeated treatment with small quantities of iodine until it no longer gave rosaniline on heating with nitrobenzene) was half neutralised with HCl and heated with *p*-nitrotoluene and Fe Cl<sub>3</sub>, a good yield of rosaniline was obtained, and the distillate contained benzene. The same result was obtained by the employment of *o*-nitrotoluene, *p*-nitrotoluenesulphonic acid, dinitroxylylene, and trinitroxylylene, the rosaniline formed being in all cases identical. With dinitroxylylene and trinitroxylylene an evolution of methylchloride and chlorinated derivatives of methane was noticed during the reaction.

—A. G. G.

*Cochineal and Cochineal Carmine.* C. Liebermann. Ber. 18, 1869.

The present state of the literature of this subject is very defective; for instance, the author finds that the finest kinds of cochineal contain only about 10% of pure colouring matter, whereas the percentage usually given is 34–50, and also in many other points arrives at conclusions different from those previously given. The percentage of colouring matter in ordinary cochineal was determined by precipitating the aqueous solution with lead acetate, purification of the lead compound, determination of the lead contained in it, and of the colouring matter by difference. Cochineal carmine is insoluble in alcohol, and nearly insoluble in water. An analysis of a very pure specimen gave the following results:—

Water.....	17 per cent.
Nitrogenous substances.....	20 "
Colouring-matter .....	56 "
Ash .....	7 "
Wax .....	traces.

The nitrogen, which amounts to about 3.7% on the dry carmine, is probably chiefly present as albuminous substances, since on fusion with KOH a smell of indole is produced. The ash contained—

Al <sub>2</sub> O <sub>3</sub> .....	43.1 per cent.
CaO.....	44.8 "
MgO.....	1.0 "
Na <sub>2</sub> O .....	3.2 "
K <sub>2</sub> O .....	3.6 "
P <sub>2</sub> O <sub>5</sub> .....	3.2 "
SiO <sub>2</sub> .....	7 "

and small traces of Fe, Cu, and SiO<sub>2</sub>; the tin and copper are probably only accidental impurities. The Ca, Al, and Mg are present in the proportion

analogous to the proportion of Al to Ca found by Kopp in fabrics dyed with Turkey-red. The dyestuff dissolves in

ammonia to a clear solution from which the Al and Ca cannot be precipitated. On heating the dry carmine to 180° it is converted into rufoearmine, and at a still higher temperature (250°) evolves CO<sub>2</sub>, apparently showing that the dyestuff is a carboxylic acid. The author could obtain no confirmation of the statement that the dyestuff is a glucoside.—A. G. G.

*On the Wax and Fat of Cochineal.* C. Liebermann. Ber. 18, 1975.

THE statement that cochineal contains stearin and margaric is erroneous. The author has separated a wax and a fat neither of which contain the above bodies. The wax is obtained by extracting the cochineal with benzene, and consists almost entirely of a substance to which the author gives the name coccerin. After the removal of the coccerin the fat is extracted with ether; it consists of myristin and an oil containing fatty acids. The following are the percentages of coccerin in various samples of cochineal (extracted with benzene whole):—

Silver cochineal .....	1.0 per cent.
Mexican silver cochineal .....	1.7 "
Teneriff silver cochineal .....	2.0 "
Zaccatille .....	0.5 "
Teneriff black cochineal.....	0.7–1.0, "
Mexican black cochineal.....	1.5 "
Granilla.....	4.2 "

By powdering the cochineal before extraction the percentages increased by about one-half, except in the case of Granilla, where the granules are exceedingly small. The percentage of myristin is on the average about 1.5–2.0, and of fluid fat and fatty acids 4.0–6.0, so that the average total quantity of wax and fat contained in a silver cochineal is about 12%. After recrystallising from benzene or acetic acid coccerin forms thin glistening plates of melting point 106°, it is sparingly soluble in all cold solvents and nearly insoluble in alcohol and ether. It has the constitution C<sub>30</sub>H<sub>48</sub>(C<sub>21</sub>H<sub>31</sub>O<sub>3</sub>)<sub>2</sub>. On saponification with alcoholic KOH it gives cocceric alcohol C<sub>30</sub>H<sub>48</sub>(OH)<sub>2</sub> and cocceric acid C<sub>21</sub>H<sub>31</sub>O<sub>3</sub>. The alcohol forms a white crystalline powder of melting point 101–104°. The acid melts at 93° and is soluble in hot alcohol, benzene, etc.; its ethyl ether melts at about 70°. The myristin C<sub>21</sub>H<sub>31</sub>(OC<sub>21</sub>H<sub>31</sub>O<sub>3</sub>)<sub>2</sub> forms colourless crystals of melting point 55°, easily soluble in warm alcohol, etc.; on saponification it gave glycerol and myristic acid C<sub>17</sub>H<sub>33</sub>O<sub>2</sub> of melting point 54° and boiling point 248° at 100mm.—A. G. G.

*Improvements in the Manufacture of Extracts and Liquors of Logwood.* C. E. Avery, Florida, U.S. Eng. Pat. 7630, June 23, 1885.

THIS process consists in heating the logwood with chlorates or nitrates to the boiling point, or preferably under pressure at heats above the boiling point. A logwood yielding 10% hamatoxylin requires about 1.4% of its weight of KClO<sub>3</sub> or nearly 3% of NaNO<sub>3</sub>. The inventor claims that by this method the hamatoxylin is completely oxidised to hamatin, and that therefore there is no necessity for the use of oxidising substances in the subsequent dyeing or printing; and hence no loss by precipitation in the dyeing and no risk of tendering in the steaming after printing. He claims also that the colour yielded is fast. Hypochlorites acting in the cold give the same result, but are not so uniform in their action.—J. H. H.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*Improvements in the Treatment of Cotton Seed for the Removal of Fibrous Matter therefrom, and an Apparatus therefor.* William Henry Stead. Eng. Pat. 13,831, October 20, 1884.

COTTON-SEED is placed in a cylindrical pan having a perforated false bottom. Through the bottom of the pan a vertical shaft armed with stirrers passes; this can be driven at any speed by suitable gearing. The seed is

moistened with strong sulphuric acid and the stirrers set in motion. The proportion of acid varies from  $2\frac{1}{2}$  to 4lb. per 100 of seed. The stirring is continued until the fibres surrounding the seed are detached from the seeds in the form of a fine powder: this escapes through the false bottom and through a spout provided for the purpose. The seed is then sprinkled with powdered lime, the stirring being continued. The excess of acid is thus removed as a fine powder of sulphate of lime and the seed is left clean. A thin coating of lime dust remains, however, which can be easily removed by means of a brush and screen. A drawing accompanies the specification.

—E. J. B.

*An Improved Process for Treating old cotton, or other Ropes, and Cotton or other Waste, to be used as Engine-cleaning Waste.* H. M. Semmons and V. Nathan. Eng. Pat. 14,338, October 30, 1884.

The patentees open—if required—the ropes or other waste by the usual methods, and then dye the materials with aniline or other dyes. They claim that the dyeing “removes or counteracts the grease in the materials and leaves the waste in a better condition for absorbing oil” when used as engine-cleaning waste.—J. H. H.

*Improved Apparatus for Wool-washing.* L. A. Groth, London. From A. Mouchablon, Paris. Eng. Pat. 14,962, November 13, 1884.

THE inventor proposes a mechanical arrangement for a continuous operation. For particulars and drawing of the arrangement the original specification should be consulted.—H. A. R.

*Treating Animal and Vegetable Fibres for Textiles, Cordage, and other Uses.* Wesley Washington, Hamilton. Eng. Pat. 6922, June 8, 1885.

IN this invention animal fibres, as cow-hair and vegetable fibres, like short jute or short flax, etc., which by reason of their structure and length are unsuitable for spinning and weaving purposes, are treated in such a way as to render them suitable for these purposes. The method consists in subjecting the fibres to great pressure in one or more directions. The fibres thus treated are found to possess a certain amount of curliness which greatly improves their spinning properties. The fibre, say, for example, jute, in lengths of about two inches, is shaken up in order to intermingle the fibres and then closely packed in a strong iron cylinder. It is then subjected to such pressure that 65lb. are forced into a space of one cubic foot, for about five minutes. The mass of fibres is then removed and is replaced in the cylinder in such a way that those portions previously occupying a vertical position are now placed horizontally—pressure being again applied as before.—E. J. B.

*Treating Animal and Vegetable Fibres for Textiles, Cordage, and other Uses.* Wesley Washington Hamilton. Eng. Pat. 6923, June 8, 1885.

THIS patent differs from the preceding one in that the mass of fibres, after having undergone the pressure treatment, is then tightly bound with cord or wire and boiled in water for one hour. The fibres are then opened out by hand and carefully dried.—E. J. B.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Contribution to the Chemistry of Morphants. On the Behaviour of the Solutions of some Salts of Chromium.* L. Liecht and H. Schwitter. Mitth. des Techn. Gewerbe-Museums in Wien, May, 1885. (Compare this Journal, 1883, 537.)

IN this paper the authors have studied the behaviour of the solutions of some salts of chromium, the object being to obtain some useful data for the dyeing and printing industries. Normal and basic sulphates, thiocyanates,

acetates, sulphacetates, nitro-acetates and chloro-acetates were prepared from chrome alum and chromium sulphate. The behaviour on dilution and heating, as well as towards the fibre during mordanting, hanging and drying, was studied. Experiments were also made having regard to the action of precipitants on these mordants. The results obtained are embodied in a series of tables, which are now given in a more condensed form. (See pp. 588–591). From these tables it will be seen that the normal salts are not dissociated either on boiling or dilution. The basic sulphates are decomposed on diluting. A number of basic acetates, sulphacetates and nitro-acetates were dissociated, whilst the sulphate, thiocyanate and chloro-acetate mordants were not affected. It is further shown that the more basic the mordant the more readily it is decomposed on dilution with water and heating. Owing to the imperfect separation of the chromium, it was impossible to determine the end of the dissociation. The quantity of chromium oxide retained by the fibre during the operations of mordanting, drying and ageing was found to increase with the basicity of the mordant, the strongly basic sulphates yielding the largest quantity of oxide to the fibre, but numbers as high as in the case of some aluminium mordants were not obtained. The behaviour of chrome alum mordants differed from that of chromium sulphate mordants, a circumstance which affords further proof of the influence of potassium sulphate on the mordants prepared from chrome alum. In their previous communication the authors showed that only those basic aluminium acetates which contained a sulphate in solution were decomposed on dilution with water, and in this respect the behaviour of chrome alum mordants agrees with alumina mordants. In regard to the influence of precipitants, it was found that the results differed according as the solutions of the various mordants had been freshly prepared or kept for some time; for instance, freshly prepared chromium acetate resisted the action of precipitating agents more powerfully than after it had been kept. The authors consider that the changes of colour exhibited on heating the mordant solutions are due to the production of basic salts, and not the formation of modifications of chromium hydroxide.—D. B.

*Use of Ammonium Carbonate for fixing Alumina Mordants on Cotton.* J. Wolf. Mitth. des Techn. Gewerbe-Museums in Wien, May, 1885.

THE author has made a series of successful dye tests with ammonium carbonate as a fixing agent for alumina mordants. The advantage gained by the use of this substance is said to depend on the circumstance that pure aluminium hydroxide is produced on the fibre, whilst with the usual cow-dung surrogates basic phosphates, arsenates, etc., are formed, the acids of which are less readily expelled, so that the operation of dyeing is prolonged. The action of ammonium carbonate was tried on the following mordants. The latter were made to contain 100grm.  $Al_2(SO_4)_3 + 18H_2O$  in a litre:—

1. Aluminium acetate  $Al_2Ac_2$ . The results were the same whether 5 or 10grm. of carbonate was added to one litre of the mordant. A temperature of  $50^\circ$  gave the best results. The action is more favourable with 20grm. carbonate per litre, and the best results are obtained with 40grm. in a warm solution.

2. Aluminium sulphacetate  $Al_2SO_4Ac_2$ . As in the former case an increase in the amount of carbonate employed intensifies the colour, the best result being obtained when 40grm. of carbonate are used in a cold or warm solution.

3. Basic aluminium sulphate-thiocyanate— $Al_2(SO_4)(CNS)_2(OH)_2$ .

In this case satisfactory results were obtained with less concentrated fixing baths.

4. Basic aluminium thiocyanate  $Al_2(CNS)_2(OH)_2$ . Good results were obtained with smaller additions of carbonate than in the case of mordants 1 and 2.

It is recommended to try experiments on a large scale in this direction.—D. B.

*On the Behaviour of Compounds of Aluminium in the presence of Alizarin.* L. Liechti and W. Suida. Mitth. de Techn. Gewerbe-Museums in Wien, May, 1885.

THE authors have investigated the changes occurring in the practical operations of dyeing and printing with alizarin. The following is a summary of their observations:—

1. Pure aluminium hydroxide *per se* or in the form of a mordant is not dyed by alizarin unless a salt of calcium is present.

2. Normal aluminium alizarate  $\text{Al}_2\text{O}_3(\text{C}_14\text{H}_6\text{O}_5)_2$  is obtained by the addition of aluminium sulphate to an ammoniacal solution of alizarin. It is soluble in water, alcohol and ammonia.

3. Basic aluminium alizarates. The following were prepared:—

(a)  $\text{Al}_2(\text{C}_14\text{H}_6\text{O}_5)_{1.5}(\text{OH})_{1.5}$ , insoluble in water, soluble in ammonia.

(b)  $\text{Al}_2(\text{C}_14\text{H}_6\text{O}_5)(\text{OH})_4$ , insoluble in water and ammonia.

(c)  $\text{Al}_2(\text{C}_14\text{H}_6\text{O}_5)_{0.75}(\text{OH})_{2.25}$ , insoluble in water, sparingly soluble in ammonia.

All basic alizarates are insoluble in alcohol.

4. Normal calcium alizarate,  $\text{C}_14\text{H}_6\text{CaO}_4$ , is obtained by the double decomposition of calcium acetate or chloride and an ammoniacal solution of alizarin. It is a crystalline body, is sparingly soluble in water and is readily decomposed by acids (even oleic acid).

5. Basic calcium alizarates are produced by employing an excess of alizarin. They are soluble in cold water and ammonia. On heating the solution the normal salt is separated and a solution of ammonium alizarate obtained.

6. Excess of alizarin prevents the precipitation of aluminium salts by ammonia.

7. Aluminium calcium alizarates are obtained by dyeing aluminium hydroxide with alizarin in the presence of calcium salts. The following compounds were prepared:—

(1.)  $(\text{Al}_2\text{O}_3)_2(\text{CaO})_4(\text{C}_14\text{H}_6\text{O}_5)_4$

(2.)  $(\text{Al}_2\text{O}_3)_3(\text{CaO})_5(\text{C}_14\text{H}_6\text{O}_5)_5$

(3.)  $(\text{Al}_2\text{O}_3)_3(\text{CaO})_5(\text{C}_14\text{H}_6\text{O}_5)_{7.5}$

(4.)  $(\text{Al}_2\text{O}_3)_3(\text{CaO})_5(\text{C}_14\text{H}_6\text{O}_5)_{6.75}$

(5.)  $(\text{Al}_2\text{O}_3)_3(\text{CaO})_{1.2}(\text{C}_14\text{H}_6\text{O}_5)_{3.6}$

(6.)  $(\text{Al}_2\text{O}_3)_3(\text{CaO})_{2.5}(\text{C}_14\text{H}_6\text{O}_5)_{6.45}$

(7.)  $(\text{Al}_2\text{O}_3)_3(\text{CaO})_{1.5}(\text{C}_14\text{H}_6\text{O}_5)_4$

(8.)  $(\text{Al}_2\text{O}_3)_3(\text{CaO})_{1.2}(\text{C}_14\text{H}_6\text{O}_5)_{3.6}$

(9.)  $(\text{Al}_2\text{O}_3)_3(\text{CaO})_{1.1}(\text{C}_14\text{H}_6\text{O}_5)_{3.3}$

(10.)  $(\text{Al}_2\text{O}_3)_3(\text{CaO})_{1.1}(\text{C}_14\text{H}_6\text{O}_5)_{3.3}$

All these lakes are insoluble in water. Nos. 1, 2, and 3 are readily soluble in ammonia; 4, 5, and 6, partially soluble in ammonia; whilst Nos. 7, 8, 9, and 10 are insoluble in ammonia. It is remarkable that lake 1 is readily soluble in ammonia and lake 9 insoluble, seeing that the composition of both is the same.

8. The formation of aluminium calcium alizarates shows that the absorption of lime by the lake depends on the amount of alizarin employed, although the absorption of alizarin is limited by the quantity of calcium present.

9. In most cases alizarin and Turkey-reds contain a large excess of alumina in comparison with the amount of lime and alizarin present.

10. On dyeing cloth mordanted with alumina in a bath of alizarin and calcium acetate, 1 mol. alizarin absorbs 4 mol. lime.

11. The most probable formula for normal alizarin red (not soaped) is  $(\text{Al}_2\text{O}_3)_3(\text{CaO})_4(\text{C}_14\text{H}_6\text{O}_5)_4\text{H}_2\text{O}$ .

12. This lake dissolves readily in ammonia, and its solution can be mixed with Turkey-red oil without being altered.

13. The compound  $(\text{Al}_2\text{O}_3)(\text{CaO})_2(\text{C}_14\text{H}_6\text{O}_5)_2$ , described by Saget as alizarin or Turkey-red, is soluble in water.

14. This substance is not produced during the dyeing operation, even under pressure, but a basic lake is invariably formed.

15. On treating these lakes with Turkey-red oil, fatty hydroxy-acids are absorbed from the oil by the lakes. The sulphuric acid, set free by the decomposition of the

fatty sulphuric ether, decomposes a corresponding quantity of the lake. Alizarin is liberated and the sulphates of calcium and aluminium are formed.

16. The ratio of lime to alumina is altered during the soaping process in the case of alizarin-reds as well as Turkey-reds. Alizarin-reds absorb fatty acids from the soap during this operation.—D. B.

*Preparation of Carmine.* L. Sedna. D. Ind. Zeit. 26, 105.

IN making carmine, care should be taken that the materials used are free from iron, that the water is soft, or better, distilled, and that soap has not been employed to wash the linen used. Temperature and light influence the colour of the product, the brightest tint being obtained when there is a maximum amount of sunshine. Madame Cenette recommends boiling 1 kilo. of the cochineal with 75 kilos. of distilled water for two hours, then adding 25 grm. of pure saltpetre, and finally, after three minutes, 30 grm. of oxalic acid. The whole is allowed to stand for three weeks, the liquid removed as far as possible by means of a pipette, and the carmine carefully dried. Carmine is readily soluble in ammonia, and is reprecipitated from this solution by acetic acid and alcohol. As starch and cinchabar are the common adulterants, the carmine can be dissolved out by ammonia, and the residue weighed to give the amount of impurity present.—S. R.

*A Black Stain for Wood.* Chem. Centr. 16, 543.

5 KILOS. of logwood and 4 kilos. of gallnuts are mixed with 18 litres of good vinegar, and the mixture allowed to stand for a week. At the end of this time 5 litres of water are added, and the whole evaporated to 10 litres in volume, and the clear liquid poured off. In another vessel 1 kilo. of iron filings are heated with 5 litres of good wood vinegar, and the mixture stirred from time to time until the temperature rises to 16° C. The two liquids obtained in this way are mixed, and the pieces of wood to be stained are kept in the solution until the requisite colour is obtained.—S. R.

*The Bleaching and Colouring of Straw.* E. J. Hödl. Chem. Centr. 16, 375–376.

THE natural colouring matter of straw can be removed by treatment with warm water and a weak ley containing 8 parts potash and 12 parts soda to 50 parts water. The straw is afterwards washed two or three times with still weaker alkali, and finally with warm water. The bleaching process consists in treating the straw first with chlorine, and then with sulphurous acid. But generally a delicate straw shade is required, and to obtain this, the already bleached material is immersed in a bath containing 1.5 grm. of picric acid dissolved in 10 kilos. of water. If, however, a pure white straw be desired, the partially-bleached material is treated with warm water, then with a dilute soda ley at 50° C. and afterwards in a chloride of lime bath. To this bath dilute hydrochloric acid is subsequently added, and the straw is removed after half-an-hour. Finally it is washed in a bath of one per cent. soda solution. The straw bleached by this method is pure white in colour and very pliant and elastic. The following recipes for dyeing straw are given. The quantities recommended in each case are sufficient to dye 10 kilos. of straw. Black: Heat for two hours in a solution of 2 kilos. log-wood and 500 grm. sumach, then in a bath of ferric nitrate solution at 4° B. Another method is to add 125 grm. of curcuma to the first solution, and substitute ferrous sulphate for ferric nitrate in the second. Grey: The straw is treated with sodium carbonate solution and a little lime, then with a solution of 2 kilos. alum and 100 grm. tartaric acid. For special shades a little cochineal or indigo carmine is added. A little sulphuric acid is added to neutralise the cochineal, and the straw is finally washed in acidulated water. Brown: Heat for two hours with 750 grm. sandal-wood, 1 kilo. curcuma, 250 grm. sumach, and 600 grm. log-wood, and sadden the shade so obtained in a bath of copperas. Or, use 370 grm. sandal, 500 grm. curcuma,

—D. B.

100.grm. sumach, and 350.grm. log-wood, and afterwards soak the straw in a solution containing 2–3kilos. of alum, and remove when the colour is sufficiently intense. Violet; heat for two hours with 2kilos. alum, 500.grm. tartaric acid, and 500.grm. stannous chloride. Straw can be very readily coloured with most of the aniline dyes, and can afterwards be rendered glossy with either gum or gelatine.—S. H.

*Improvements in Dyeing Fabrics Aniline Black and in Apparatus therefor.* C. R. Preibisch. Eng. Pat. 12,472, September 6, 1884.

THE patentee has devised a new form of apparatus for the oxidation of aniline black which, he claims, gives an excellent black that does not rub off, and obviates all danger of the streakiness which appears in blacks oxidised by hanging in damp air. The apparatus is somewhat similar in form to the large continuous steaming apparatus of Messrs. Mathier & Platt. The fabric saturated with the mordants is dried in the front part of the apparatus by means of a current of warm air which, by the aid of fans, is made to circulate between the folds of the cloth, and in the latter part is oxidised at a temperature of 44–50° C., the atmosphere of this portion being kept moist by the use of water troughs at the bottom of the apparatus. By means of guide rollers, the cloth is kept at a perfectly even tension, and proceeds at a uniform rate throughout. Noxious gases are removed as soon as formed by exhaust pipes along the roof. Aniline black on delaines can also be oxidised in this way, and the wool fibres left in a fit condition for subsequent dyeing with log-wood.—J. H. H.

*A New Method of Dyeing Silk and Woolen Fibres with Insoluble Azo-colouring Matters.* Dan Dawson and G. W. Oldham. Eng. Pat. 13,211, October 6, 1884.

THE inventors have found that if a precipitated naphthol or similar body is added to a weak neutral solution of a diazo-compound, a bath is produced which slowly and gradually deposits an azo colouring matter. Presence of a slight excess of acetic acid further retards the reaction. Thus a 0.1 per cent. solution of xylydine or naphthylamine hydrochloride in excess of HCl, is azotised by means of a weak solution of NaNO<sub>2</sub>; when the reaction is complete, pure chalk is added till the liquid is neutralised, and then at least 0.1 per cent. finely-precipitated naphthol along with acetate of soda and a little acetic acid. Silk or wool immersed in this bath are effectively dyed, and the rapidity of the operation may be regulated by the addition of a larger or smaller quantity of acetic acid.—J. H. H.

*A New or Improved Process for Cold Scouring and Dyeing Cotton.* W. H. Beck. From La Société Ch. Taussant et Cie., Paris. Eng. Pat. 13,258, October 6, 1884.

THE patentee acts upon cotton in cops and fleeces in a vacuum apparatus with a 1 per cent. solution of what appears to be a very alkaline "soluble oil" of 50 per cent. strength. If the cotton is in hanks or skeins, the same solution is used, but in the open air. The dyeing operation for cops and fleeces is also conducted in a vacuum: for hanks and skeins in the open air in the ordinary way. If light shades are required to be dyed, ammonia or a carbonated alkali is used in the scouring, and the cloth is soured and washed before dyeing.

—J. H. H.

*Improvements in Bleaching.* C. F. Cross and J. P. Rickman. Eng. Pat. 13,678, October 16, 1884.

THE cotton or linen goods, having been boiled with lime or alkali in the ordinary way, or steamed according to a former patent (Cross, 4984, Nov. 30, 1884), are immersed in an alkaline solution containing, preferably, about 1 per cent. Na<sub>2</sub>O. Milk of lime may also be used. Excess of moisture is then removed, and the goods placed in an

air-tight kier: from this the air is withdrawn and replaced by chlorine gas, with which the goods are allowed to remain in contact until the action is completed: or, if necessary, the goods may be again immersed in the alkali, and again treated with the chlorine. The process is best carried on in an apparatus similar to that patented by Thompson (595, Feb. 3, 1883), or in the case of piece goods in the apparatus patented by Mather (7909, May 19, 1884). In the latter case, alkaline solutions may be printed on the cloth, and the effect of a topical discharge produced by passing through the chlorine gas for a few seconds.—J. H. H.

*A New Process of the dyeing Black on Cotton, Cotton Yarns, or Cotton Fabric, or other Vegetable Fibre.* J. Clare. Eng. Pat. 14,225, October 28, 1884.

THE goods are passed through log-wood liquor at 4° F., the excess of moisture removed, after which they are passed through a bath of copperas and alkaline sulphide, the use of the latter being the distinctive feature of the process.—J. H. H.

*Improvements in Dyeing with Aniline Black.* W. P. Thompson. From A. Descroix, of Villefranche. Eng. Pat. 14,276, October 29, 1884.

THIS process is applicable to woven fabrics and all kinds of textile material. A cold solution of aniline and a soluble bichromate, is printed or padded on the material, which is then wound upon a small roller, and left until the black is sufficiently developed: this requires from fifteen minutes to fifteen hours, according to the strength of the solution. The goods are then washed, soaped and finished as usual, and it is claimed that no tendering of the material takes place. The best proportions are two parts of bichromate to one part of aniline dissolved in sufficient acid to "saturate the alkali of the bichromate."

—J. H. H.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Communication on Certain English Chemical Industries.* Chem. Zeit. 9, 551 and 569.

*Chrome Green* (Guignet's green).—The materials employed for the manufacture of chrome green are acid potassium chromate and boric acid, which on heating give chromium oxide and potassium borate. It is necessary to subject the commercial boric acid to a process of purification which is best effected by dissolving the acid in water, treating the resulting solution with animal charcoal, and allowing the clear solution to crystallise. The crystallised mass is dried in centrifugal machines. The mother-liquor may be employed for dissolving fresh portions of boric acid, but should not be used more than four or five times. The charge consists of eight parts boric acid and three parts acid potassium chromate, both being in a finely-divided and intimately-mixed state. The furnace is so constructed that the flame first passes over the charge, and is then led away under the bed of the furnace. For each operation about 45kilos. of the above mixture is taken, the roasting being completed in about four hours. The temperature should not exceed that of a dark-red heat. The fused mass is thrown into water and washed repeatedly by decantation, the first and second wash waters being reserved for the recovery of the boric acid, whilst the third washings are used as water for the first extraction. The purified pigment is then placed on cotton filters, allowed to drain and passed through colour mills (wet mills). After grinding the mass is again washed with hot water, filtered and pressed, so that a product is obtained which contains 33 per cent. of dry matter, and yields 26 per cent. of residue when ignited. For the recovery of the boric acid the washings are evaporated in leaden pans to 13° B. and treated with hydrochloric acid, potassium chloride and boric acid being obtained. The latter crystallises out on cooling. The mother-liquors are concentrated to 20° B. The crystals which are thrown out are dissolved, and the solution is treated with hydrogen sulphide to remove the

lead absorbed by the liquors. The mixture is filtered, the solution evaporated and allowed to crystallise. Only 65 per cent. of the boric acid originally employed is recovered.

*Tin Salt.*—The action of hydrochloric acid (which must be free from iron if a pure product is required) on tin is effected in stone vats capable of holding 400kilos. of tin, and 875kilos. hydrochloric acid of 20° B. Having introduced the charge it is heated gently for twelve hours, after which it is drawn off and allowed to settle. The clear solution is then concentrated in copper pans to 65° B. and allowed to crystallise. The crystals are dried on slate slabs or by centrifugal machines. In order to prevent the action of the tin solution on the copper pans it is necessary to have free tin constantly in the pan. The casks used for packing the crystals are lined with paper saturated with paraffin.

*Sodium Stannate.*—Ten half-round cast-iron boilers 0.75m. in diameter, and grouped together in horse-shoe form, are built in brickwork and heated gently by a furnace placed at one end of the series. A metal tube is fixed in the centre of each boiler, the lower end of which forms a perforated funnel. A syphon is dropped into the tube at the end of the operation in order to withdraw the tin solution. Each boiler is almost filled with granulated tin, and six out of the ten boilers are charged with soda ley of 15° B. The liquor is then passed from one boiler to the other until it shows a density of 30° B., when it is drawn off into an iron tank and allowed to settle. In order to prepare the "sodium stannate liquor," the solution is treated with the requisite quantity of common salt to reduce the amount of tin to 5 per cent., whilst for the production of the solid salt the solution is evaporated to dryness in a cast-iron boiler. After calcining the residue the dried salt is mixed with common salt, so that a product containing 42 per cent. of tin is obtained.

*Nitric Acid.*—For the manufacture of nitric acid cast-iron cylinders 0.75m. in diameter and 2m. in length, or cast-iron stills 3m. long, 1.4m. wide, and 0.9m. high, lined with stone slabs and set in brickwork, are used. The charge consists of 250kilos. of saltpetre and 310kilos. sulphuric acid of 60° B.

*Arsenic Acid.*—This acid is prepared by the action of nitric acid on arsenious acid. The operation is effected in stone vats, holding from 65 to 70kilos. of arsenious acid.—D. B.

*Solubility of Tin Mixtures.* Fr. Rüdorff, Sitzber. der Berl. Akad. der Wissenschaft, 1885, 355.

A LARGE excess of the two salts, finely-powdered and mixed, was warmed with a known quantity of water, repeatedly shaken, and then allowed to cool to the temperature of the room. Three equal portions of this solution were taken, and to the first a known weight of one of the salts was added, and to the second a like quantity of the other salt, the third remaining unchanged. The three solutions were frequently agitated, and after some time filtered from the separated crystals and analysed. Two series of experiments were conducted. 1. When no chemical interchange was possible, as when two salts with the same acid or base were mixed. 2. When a double decomposition was possible, as when salts with two acids and two bases were mixed. This paper was confined to the consideration of the first of these two classes of reactions. When the two salts used were capable of uniting to form double salts—*e.g.*, ammonium and aluminium sulphate—there was a marked displacement of one constituent salt by the other, or rather a displacement of the double salt by one of its constituents. This was shown by adding one of the constituent salts in a finely divided state to a saturated solution of the double salt. The same was the case with isomorphous salts, but with mixtures of salts which neither formed double salts nor were isomorphous no displacement of the one by the other was noticed. A molecular attraction exists then between the constituents of double salts, and between salts of the same isomorphous group, different from that between any two salts. The fact that double salts crystallise better from a solution which contains an excess of one of the two constituents is explained by these experiments. These phenomena can

be shown in the case of isomorphous salts by the growth of a crystal of chrome alum in a saturated solution of ordinary alum, and by suspending a crystal of calc spar in a solution of ferrous carbonate in water charged with carbonic acid.—S. R.

*On the Existence of Nitrous Anhydride in the Gaseous State.* G. Lunge. J. Chem. Soc. (Trans.), 1885, 457.

This paper is entirely controversial, and the author criticises adversely the methods of experiment and the conclusions deduced in the researches of Ramsay and Cundall on the above subject, and complains that his own results had been overlooked by the later experimenters, who had adopted opposite views without disproving results previously published. The author maintains the validity of his deductions, which are to the effect that  $N_2O_2$  may exist in the gaseous as well as in the liquid state. His argument as against his opponents is that their material must have been impure, and was obtained only by passing NO through a solution consisting practically only of  $N_2O_2$ , thus giving a source of error sufficient to invalidate their conclusions, and the accuracy of the analytical methods employed is also called in question. The author states that his own researches were conducted with nearly pure  $N_2O_2$ , which only partially and with difficulty combined with free oxygen present in large excess to form  $N_2O_4$ . This, together with his statement that the gases escaping from vitriol chambers under normal conditions contain a large excess of free oxygen, although the nitrogen compounds are present only as  $N_2O_3$ , form his main argument for his own conclusions.—G. H. B.

*On the Reaction between Nitric Oxide and Oxygen under Varying Conditions.* G. Lunge. J. Chem. Soc. (Trans.), 1885, 465.

IN order to bring further facts to bear upon a controversy carried on by the author in a preceding paper, some experiments are described from which he formulates the following conclusions:—1. In the dry state, nitric oxide with an excess of oxygen combines to form  $N_2O_4$  exclusively, or nearly so. 2. Dry nitric oxide and oxygen, with an excess of the former, yield a great deal of  $N_2O_3$  along with  $N_2O_4$ , both in the state of gas. 3. In the presence of water, nitric oxide, with an excess of oxygen, is altogether converted into  $HNO_3$ . 4. If nitric oxide and oxygen meet in the presence of concentrated sulphuric acid, there is neither  $N_2O_4$  nor  $HNO_3$  formed even with the greatest excess of oxygen, but the reaction is  $2SO_3 + 2NO + O = 2SO_2 \cdot (OH)(NO) + H_2O$ . Further, it is not NO, but  $N_2O_3$ , which acts as carrier of the oxygen in the vitriol-chamber process. An addendum contains a reply to a criticism made at the reading of the paper, in which the author contends that in the gaseous state the  $N_2O_3$  once formed is not oxidised by any excess of free oxygen, the same for the liquid  $N_2O_3$  having been shown by other observers.—G. H. B.

*On some Sulphur Compounds of Calcium.* V. H. Veley. J. Chem. Soc. (Trans.), 1885, 478.

AFTER a historical retrospect of work done by others in the same field, the author describes in detail his experiments on the reactions of sulphuretted hydrogen over carbon disulphide upon lime, both in the dry and wet way. Careful elimination of impurities in the materials and precautions against outside influences are described, and the numerical results show a close accordance with the conclusions drawn. The author observed that perfectly-dry calcium oxide was unaltered by perfectly-dry hydrogen sulphide, and the main points of his paper he summarises as follows:—1. By the action of hydrogen sulphide on solid calcium hydroxide there is formed a calcium monosulphide in accordance with the equation—

2. By the action of hydrogen sulphide on calcium hydroxide in aqueous solution there is formed calcium hydrosulphide in accordance with the equation—

3. Calcium hydroxyhydrosulphide  $CaSH \cdot OH$  absorbs carbon disulphide with formation of unstable basic calcium thiocarbonates, decomposed slowly by hydrogen sulphide, and readily by carbonic anhydride.—G. H. B.

*Action of Ammonia on Solutions of Potassium Salts.* H. Girard. Chem. Centr., 16, 529 and 530.

MOST potassium salts are less soluble in water saturated with ammonia, than in pure water. Some salts—e.g., sulphate, oxalate, ferrocyanide and phosphate—are partially precipitated when ammonia gas is passed into their saturated solutions. The chloride, nitrate, and chlorate are not so precipitated. When ammonia gas is passed into a very concentrated solution of potassium carbonate, no precipitate is formed, but the liquid separates into two layers, of which the upper contains the greater part of the ammonia, and the lower nearly all the carbonate. When strong ammonia solution is added to dry potassium carbonate, two layers are formed and a large quantity of ammonia is evolved. A saturated solution of potassium carbonate is not miscible with strong ammonia solution until a few drops of water be added. The volume of the two layers varies with the temperature. This can be more easily seen by colouring the upper layer violet with orseille red, which has no action on the lower layer. 29° C. appears to be a critical temperature, above which the two layers unite. On cooling below this temperature the liquid first becomes turbid, and then gradually separates into two layers. Potassium sulphate is the least soluble of all the potassium salts in aqueous ammonia. The author has determined the solubility of potassium sulphate in water containing different amounts of ammonia, and from his data a curve can be constructed. Both ammonium and sodium sulphates are easily soluble in aqueous ammonia, so that a solution of sodium or ammonium sulphate in saturated ammonia solution gives, with solutions of a potassium salt in saturated ammonia solution, a precipitate of potassium sulphate. Weak solutions of potassium salts which give precipitates neither with sodium bitartrate nor with platinum chloride (without the addition of alcohol), are easily thrown down if the solution be first saturated with ammonia and an ammoniacal solution of sodium sulphate added. This reaction cannot, however, be used quantitatively.—S. R.

*Sodium Hypochlorite.* Egmont Kutschera. Mitth. des Techn. Gewerbe-Museums in Wien, May, 1885.

IN a paper on Bleaching according to Thompson's Process, in the *Centralblatt Textil-Ind.*, November, 1884, it is stated that in decomposing bleaching powder with sodium carbonate in order to obtain sodium hypochlorite, half the bleaching power of the chloride of lime is lost. This statement is incorrect, as shown by the following equations, the accuracy of which the author has confirmed by actual experiment:—

The first equation shows that one molecule of chloride of lime liberates one molecule of chlorine on treatment with an acid, the second equation expresses the change which takes place when bleaching powder is decomposed by sodium carbonate, whilst the last equation shows that on treating sodium chloride and sodium hypochlorite with an acid the same amount of active chlorine is liberated as is evolved by the bleaching powder from which these salts were originally produced.—D. B.

*A Convenient Process for Preparing Tetrathionates of Alkalis.* N. Klobukow. Ber., 18, 1869.

THE process depends on the well-known reaction— $2Na_2S_2O_3 + 2I = Na_2S_4O_6 + 2NaI$ . Finely-powdered iodine and the thiosulphate of an alkali are put in a basin containing a small amount of water, and the mixture is stirred until solution is effected. Iodine must be present in slight excess. The syrupy solution is then

pouring into a flask, partially filled with alcohol, when a copious white crystalline precipitate of the tetrathionate is at once formed. After two to three hours the latter is collected, washed with alcohol, dissolved in lukewarm water, and, after adding alcohol, allowed to crystallise over sulphuric acid in vacuo.—S. II.

*Improvements in the Manufacture of Chromates of Soda, and in relation thereto.* E. P. Potter and W. H. Higgin, Bolton. Eng. Pat. 3229, June 29, 1883.

CHROME ore is furnace with lime and sodium sulphate. The resulting material is lixiviated with water, and the liquor obtained is treated with hydrochloric acid until it is exactly neutral, when silica and alumina are precipitated. The purified solution is then boiled down. Sodium chloride and sulphate are thrown out in the crystalline form, removed by filtering and washed with neutralised vat liquor. The strong chromate solution remaining in the pan after filtering is boiled down to dryness, and the salt perfectly dried but not fused. By this process a bichromate of soda is obtained, which also contains monochromate. If pure bichromate be required, the purified vat liquor after removal of alumina and silica is treated with a further quantity of acid in exactly the quantity required to convert the whole of the monochromate into bichromate.—S. II.

*Improvements in the Process of Manufacturing Ammonia.* A. Feldmann, Bremen. Eng. Pat. 11,711, August 27, 1884.

THE presence of lime mud in manufacturing liquid ammonia according to the usual methods considerably impedes the complete expulsion of the ammonia. The patentee, therefore, eliminates the insoluble lime compounds before distilling either by a filter-press or a centrifugal apparatus, and then proceeds in the usual manner.—S. II.

*Improvements in the Purification of Bicarbonate of Soda and Apparatus therefor.* H. Gaskell, Widnes. Eng. Pat. 11,775, August 29, 1884.

THE invention relates to the purification of bicarbonate of soda made by the ammonia-soda process, which is always contaminated with ammonia. In order to expel the ammonia by volatilisation without decomposing at the same time the bicarbonate of soda, the mixture of both compounds is heated in an atmosphere of carbonic dioxide. The patentee devised a special apparatus for this purpose.—S. H.

*Improvements in the Treatment of Certain Phosphatic Materials.* H. Brunner, Widnes. Eng. Pat. 12,718, September 23, 1884.

SUPERPHOSPHATES made from phosphatic materials containing lead, copper, manganese iron, or alumina, in conjunction with calcium and magnesium compounds, are apt to "go back," that is, the phosphoric acid becomes again partially insoluble in water. The present invention is designed to prevent this reversion by separating the foreign bases. The finely-ground material is treated with hydrochloric acid, to convert into chloride all the calcium and magnesium present. A concentrated solution of calcium chloride is then added, in such quantity that not less than three equivalents of calcium or magnesium chloride are present to each equivalent of phosphoric acid. The mixture is then dried, calcined and roasted. Hydrochloric acid is evolved and condensed for after use. The mass after cooling is lixiviated with dilute hydrochloric acid and copper or lead, precipitated with sulphuretted hydrogen. Should the solution contain iron or aluminium phosphate in any considerable quantity owing to imperfect roasting, it may be removed therefrom by digesting the solution with precipitated di- or tri-calcium phosphate, which latter goes into solution, while iron and aluminium phosphate is precipitated. The calcium or magnesium phosphate

in solution is precipitated by the addition of lime, and the remaining calcium chloride solution may be concentrated to be used in treating a fresh quantity of crude phosphates.—S. H.

*Improvements in the Manufacture of Chromic Acid or Trioxide of Chromium.* W. A. Rowell, Newcastle-on-Tyne. Eng. Pat. 12,834, September 26, 1884.

THE reaction depends on the decomposition of barium and strontium chromate by sulphuric acid. It is carried out as follows:—Strontium chromate is prepared by mutual decomposition of strontium chloride and a neutral chromate. The supernatant liquor containing some strontium chromate in solution is treated with barium chloride, whereby all chromic acid is precipitated as barium chromate. The latter is then treated with hot dilute sulphuric acid in large excess, sulphate of baryta being formed, whereas chromic and sulphuric acid remain in solution. The mixture of the two acids having been separated from barium sulphate, is treated hot with an amount of strontium chromate equivalent to the free sulphuric acid present. This results in the formation of chromic acid in solution, and the precipitation of strontium sulphate. After separating the latter from the chromic acid, the solution is boiled down to dryness at a low heat. Chromate of strontium being completely decomposed by an equivalent of sulphuric acid, this process yields directly chromic acid which is free from sulphuric acid. In place of evaporating the solution of chromic acid to dryness, it may be concentrated to a considerable strength, and then precipitated by the addition of strong sulphuric acid, the mother-liquor being afterwards used for the decomposition of a fresh quantity of chromate of strontium.—S. H.

*The Preparation of Chlorine Gas.* J. Taylor, Cheltenham. Eng. Pat. 13,025, October, 1884.

HYDROCHLORIC-ACID gas, direct from the salt-cake furnace, is passed through a tower containing fragments of pumice-stone or coke, which is kept moistened by cold strong nitric acid. Chlorine, nitrosyl-chloride, water, and small quantities of nitrogen tri- and tetra-oxides, are thus formed. The mixed gases are passed into sulphuric acid, which absorbs the nitrous fumes, permits the chlorine to pass unchanged, and decomposes nitrosyl-chloride with the formation of hydrochloric acid gas and nitrosulphonic acid. The reformed hydrochloric gas, along with the chlorine with which it is mixed, is a second time submitted to the action of nitric acid, and the gaseous products brought in contact with sulphuric acid. The resulting gas is put through the process a third time, and oftener, if required, until it is found to consist almost entirely of free chlorine. The nitrosulphuric acid formed in the process is decomposed by the gradual addition of water, whilst a rapid current of air is passed through the liquid. The nitrous vapours evolved are passed into water, whereby nitric acid is recovered, and by distilling the residual liquid containing a little nitric acid, that nitric acid is obtained, whilst the sulphuric acid is restored to its original condition.—S. H.

*Improvements in the Manufacture of Algin and other Useful Products from Seaweeds.* E. C. C. Stanford, Dalnair, County of Dumbarton, N.B. Eng. Pat. 13,433, October 11, 1884.

IN this invention improvements are proposed in the process described in Eng. Pat. 142, 1881, and consist in directly treating fresh or dried seaweed according to the "Wet Process," described in this Journal, iv. 518. The cellulose left behind having certain peculiarities, the inventor terms it Algulose. The clear solution is precipitated by dilute sulphuric or hydrochloric acid, and the crude alginic acid thereby obtained as a precipitate is washed and pressed into cakes, which are stored in a warm room where they become air-dry. The filtrate from the alginic acid is neutralised with dolly or limestone dust, the sulphate of lime precipitate

allowed to settle, and the clear solution concentrated, to allow the sulphate of soda or chloride of sodium to crystallise out. The mother-liquor is next evaporated to dryness, and the residue is carbonised to form what is called kelp extract or kelp substitute, for the preparation of iodine and potash salts. Compared with the kelp of commerce, it contains nearly double the amount of salts, and more than double the amount of iodine, and is worth more than double the ordinary market price. The iodine and bromine may be directly precipitated by adding a copper salt. The iodine may be removed by setting it free by means of nitro-sulphuric acid or chlorine, and filtering it through charcoal or by distilling it off, if it be desired to remove it first. The alginates of the alkalis and alkaline earths can be used for stiffening woven fabrics and as mordants. The blue precipitate of alginate of copper formed by precipitating a soluble algin with a copper salt is soluble in ammonia, and becomes insoluble on drying, so that it may be used for waterproofing canvas or paper. The calcium, barium and strontium salts form useful white compounds, resembling bone, which when dry may be polished and turned. A combination of alginate of ammonia with shellac forms a tough flexible substance like gutta-percha, and is capable of replacing it in some of its applications. Further details of the properties and applications of algin will be found in this Journal, vol. iii. pp. 297-302, and iv. pp. 518-520.—A. W.

*Improvements in the Manufacture of Sulphide of Zinc, and of Hydrate or other Salts of Baryta or Strontia.* H. Knight, Liverpool. Eng. Pat. 16,220, December 11, 1884.

BARIUM or strontium sulphide is precipitated with an equivalent quantity of zinc chloride. After decantation from the precipitate of zinc sulphide, the filtrate is decomposed with caustic soda or potash, whereby barium and strontium hydrate is formed, which crystallises out on cooling. If other salts of baryta or strontia be required, their respective zinc compounds are employed for precipitation.—S. H.

*Improvements in the Recovery of Ammonia in the Manufacture of Carbonate of Soda by the Ammonia Process, with Production of Sulphuretted Hydrogen.* E. W. Yarnell and J. Simpson, Liverpool. Eng. Pat. 1937, February 12, 1885.

THE residuary ammonium-chloride solution from the ammonia-soda process is heated with alkali waste in a closed vessel, whereby ammonium sulphide is given off. This vapour is brought in contact with a solution of ammonium bisulphate. Neutral ammonium sulphate is formed with evolution of sulphuretted hydrogen. After boiling down to dryness the solution of ammonium sulphate, the dry sulphate is heated to about 800° F., when it parts with a portion of its ammonia, which latter is absorbed in brine and used for the production of sodium carbonate, while the acid sulphate of ammonia which is left behind is dissolved in water and treated with a further quantity of ammonium sulphide as described above. The sulphuretted hydrogen may be employed for the manufacture of very pure oil of vitriol. In order to facilitate the liberation of ammonia from ammonium sulphate, the heating is carried out either in an atmosphere of steam or by adding to the ammonium-sulphate solution before boiling down the sulphate of an alkali, which will form an acid sulphate or bisulphate, preferably sulphate of potash. This alkaline sulphate serves merely to absorb the acid given off from the bisulphate of ammonia, and can be used repeatedly.—S. H.

*Improvement in the Manufacture of Bichromate of Potash.* P. Roemer, Elberfeld. Eng. Pat. 7135, June 11, 1885.

SODIUM bichromate is dissolved in boiling water to a concentrated solution and potassium chloride added. The whole is then maintained at the boiling point for some time. By this treatment a mutual decomposition takes

place, potassium bichromate and sodium chloride being formed. On cooling, potassium bichromate separates out. The mother-liquor is concentrated so that sodium chloride is salted out, which is removed and washed with hot water. Instead of bichromate, the neutral chromate of sodium may be employed. In this case the solution is first sufficiently acidulated with hydrochloric acid to be transformed into bichromate, when the latter is treated as described.—S. H.

*An Improved Method or Process for the Manufacture of Carbonate of Soda or Soda-ash.* H. H. Lake. From Kayser, Young & Williams, Buffalo, U.S. Eng. Pat. 7355, June 16, 1885.

THE said invention is based on the discovery that sulphate of soda, when exposed at a low red-heat to a current of carbon monoxide in the presence of a sufficient volume of carbon dioxide, is decomposed and converted into carbonate of soda, while the sulphur is driven off in the form of sulphurous acid. Sulphate of soda is prepared by the Hargreaves' process, and used in this process without removing the sulphate from the cylinders; a mixture of one equivalent of carbon monoxide, and one of carbon dioxide, is drawn by a fan through the apparatus, whereby the sulphate is converted into carbonate of soda, sulphurous acid gas being liberated, which is employed for making new quantities of sulphate of soda.—S. H.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

*Improvements in the Manufacture of Pottery.* H. M. Robinson, Minton's Limited, and Leon Arnoux, Stoke-on-Trent. Eng. Pat. 12,081, September 6, 1884.

THIS invention is for the use of compressed air in equalising the pressure during the manipulation of plastic materials in moulds or on them, and for machinery for producing such plastic materials. An incidental advantage is claimed when compression is used internally to the mould, of expelling the moisture and preventing the falling in of delicate and thin work.—T.

## X.—METALLURGY, MINING, Etc.

*Slag from Thomas's Dephosphorising Process.* C. Scheibler. Bied. Centr. 13, 411.

THE slag is prepared for the extraction from it of earthy phosphates and ferric oxide rich in manganese, by being roasted and then submitted to the action of water or steam. In consequence of the formation of calcium hydrate, the fragments of roasted slag fall to a very fine powder.—E. G. C.

*Removing Mercurial Stains from Gold.* B. Fischer. Pharm. Centr. 26, 187.

MERCURY can be removed from gold articles by a wet process, consisting in rubbing them first with a paste consisting of powdered iodine and alcohol, and then adding a concentrated solution of potassium iodide. The mercury iodide at first formed on the gold is dissolved by the potassium iodide solution. The gold is unacted upon at ordinary temperatures, and can afterwards be polished in the usual way.—S. R.

*The Selective Alteration of the Constituents of Cast Iron.* T. Turner. J. Chem. Soc. (Trans.), 1885, 474.

THE experiments described were undertaken with a view of diminishing the amount of manganese, but of leaving the silicon, if possible, unaltered, in a sample of siliceous cast iron, by exposing it in a molten state to the action of acid and basic slag. Sand and ferric oxide were employed in different proportions to furnish the different kinds of slag. It was found that but little alteration was produced by the action of sand alone, or mixed with ferric oxide, but with ferric oxide alone a marked altera-

tion in the desired direction was obtained, and still more so by the action of an air-blast. But the alteration extended generally to the other constituents of the cast iron, and the author states that "these experiments tend to confirm the practice of the present day, as showing that when it is desired to selectively alter the constituents of iron or steel it must be effected, not by attempting to eliminate some obnoxious material, which can only be accomplished by seriously altering the amounts of other elements present, but it must be done by starting from a pure metal, and adding the constituent or constituents which are desired."—G. H. L.

*An Enamel for Metals.* Pol. Notizbl. 40, 125.

A MIXTURE of 12 parts borax, 20 parts soda, and 125 parts of flint glass is fused, poured on a cold plate, pulverised, and the powder mixed with a solution of soluble glass of 50° B. The metal is coated with this paste, and then heated gently in an oven until the coating is fused, and is then allowed to cool. It adheres firmly to all kinds of iron articles.—S. L.

*Blum's Patent Method for the Recovery of Phosphoric Acid in Thomas's Steel Process.* Berg. und Hütt. Zeit. 44, 225—226.

IN this method calcined sodium carbonate, free from sulphur, is substituted for the lime lining of the Thomas process, and in the proportion of 5·13 parts of soda to 1 part of phosphorus, and 7·85 parts to 1 part of silicon present in the iron. The soda is first put in the converter and in a fused state, and then the pig iron is introduced, and the blast is turned on and kept going until the phosphorus is removed; the converter is tipped, and the slag then poured out into an iron wagon. The slag contains, in addition to sodium phosphate and silicate, iron and manganese oxides, lime, magnesia and sulphur, and can be used as a manure, or the phosphate of soda can be extracted with cold water, the soluble glass with hot water, and the residue used for the preparation of ferro-manganese. At Crenzot, with a grey iron rich in silicon, lime is added to combine with the silica, and afterwards soda to unite with the phosphoric acid. From the Crenzot slag water extracts a large quantity of sodium vanadate, which was lost by the old process.—S. L.

*Gold in the North of Japan.* R. J. Frecheville.

Proc. Inst. C.E. vol. 75.

IN the northern part of Hondu, a number of small veins, enclosed in a porphyritic rock, have been worked for gold from time immemorial at the Okadzu Mines. The veins average about one foot in width, and are filled with quartz and decomposed country rock, carrying disseminated crystals and thin bands of copper and iron pyrites, together with small quantities of zinc blende and galena. The gold is extremely finely divided, and can rarely be seen without pulverising and washing the ore. About 120 tons per month of ore, containing 1½ oz. of gold, were delivered at the floors at a cost of £4 per ton. The richest ore was crushed by a primitive stamp, then ground between flat stones like flour-milling, but worked by hand, and the slime produced was washed over a sloping board scored with saw-ends. The coarser portion, caught in a tub at the foot of the board, was ground again. The concentrations from the board were washed by hand in a shallow wooden dish, and the gold obtained was melted with borax and lead, and the product cupelled. About 50 per cent. of the gold was got by the first washing from ores assaying 20z. per ton, and about 80 per cent. from the richest class of ores, which assayed 50z. per ton and upwards. The tailings, after weathering for some time, were re-washed, yielding a further amount of gold. The author arranged a modern plant, consisting of a 10-stamp gold-mill, a slime separator "Spitz-Lütte," Rittinger's double side-blow percussion table, twelve Hungarian mills, strakes covered with scored boards to save the gold from the slimes, and two flat-bottomed iron grinding pans. The pan-amalgamation gave 90 per cent.

of the gold contained in the concentrates, and the result of the combined treatment by concentration and amalgamation was an average of 82 per cent. of the gold in the ore milled. A 40 H.P. multitubular boiler and engine, with cylinder 15½ diameter and 24 feet stroke, supplied the power.—J. T.

*Basic, Open-Hearth, Steel Process.* T. Gillett. Proc. Inst. C.E. vol. 77.

THE author made experiments, dating from May, 1882, at the Farnley Iron Company's works, near Leeds. According to Thomas and Gilchrist, pig-iron, suitable for the basic Bessemer process, should approximately contain silicon 0·5 to 1·8; phosphorus, 0·8 to 3·0; sulphur, under 0·3; manganese, not over 2·5 per cent.; and, in order to secure the necessary heat, the carbon would probably have to be 3·5 per cent.; but in the basic open-hearth process the proportion of heat-producing elements need not be high, and large quantities of wrought-iron scraps, which often contain 0·2 per cent. of phosphorus, may be converted into steel of great purity. As no basic bricks, excepting such as were too costly, were suitable for constructing the furnace throughout, the author consulted chemists as to materials which would be sufficiently refractory at a steel-melting heat, and at the same time securely isolate the dolomite lime basin of the furnace from the silica walls above. He was advised that magnesia on the lime, alumina above the magnesia, and silica brickwork carried up on the alumina, would be secure; so bricks were made from magnesite, containing 98 per cent. magnesium carbonate, and others from bauxite of the approximate composition, silica, 15; alumina, 82; lime, 1; iron sesquioxide, 2 per cent.; and with these the furnace was built in accordance with Figs. 1 to 4. This furnace had been previously used in the acid process for 50—55wt. charges. Provision was made for the removal of the slags in the early stages of the process, so that the banks of the furnace might be preserved; and any phosphorus transferred to the slags could be withdrawn, so as to reduce the amount of purification at the later stages; this provision proved very useful. The iron bottom plates A and the bridge plates B are similar to those used for the acid furnace; brackets bolted to the side-plates of the furnace support the brickwork by the plate C at the level of the top of the lime basin, and prevent settlement of the upper brickwork in case of any shrinking of the lime basin or fluxing in work. The metal tapping hole and spout is at D, and the slag tap-holes are at higher levels EE on the opposite side of the furnace. Bricks made from magnesian lime, and of the following composition—Lime, 58; magnesia, 24; silica, 8; alumina and iron oxide, 10 per cent.—are burnt at a full white heat, crushed, mixed with hot tar in a mortar mill, and are taken immediately to the furnace and rammed with red-hot rammers over the parts G, wooden plugs being inserted to form the tap-holes, the parts marked H being walled in the same bricks, and grouted with material similar to the ramming. The isolating courses I and K, of magnesian and bauxite bricks respectively, are laid on the top of the brackets C, and across the ends of the basin over the plates B; and the shape of the hearth is completed by lime ramming. The use of hot rammers is necessary to coke the tar; otherwise the lime swells and falls to pieces in about twenty-four hours after mixing. The upper part of the furnace is then completed in silica-brick. After about seventy-two hours' firing, the furnace is ready for forming the bottom, and for this a full melting heat is necessary. Well-burnt and freshly-ground magnesian limestone is laid over the bottom and up the sides, with not more than 10 per cent. of ground fire-brick added, so as to flux the lining sufficient for binding the layer forming the furnace bottom. The tap-holes are stopped by dry lime only, or dry lime mixed with a little powdered coke. The gas- and air-ports should be so arranged as to throw the flame well down on the bottom, so that the heat may be sufficient to allow of the smallest possible admixture of silicious flux. The operation is thus conducted: Fresh well-burnt lime, about one-twentieth to one-tenth of the weight of the pig-iron, is laid upon the bottom of the furnace, the pig is then charged, and

the wrought-iron or steel scraps are put on the top of the pig, all being cold. The whole of the charge if possible is placed in the furnace at the commencement. In three or four hours, the pig being melted, some slag can be tapped off. The first slag is generally very fluid, and more or less so as the silicon in the pig is higher or lower; consequently the sides of the hearth are preserved by getting rid of the more silicious slag before the full

may be raked off through the centre door, which is placed 4½ in. lower than the two end doors. About 5 per cent. of hematite pig is then charged through the end doors on the bridges, which pig, when melted, causes the metal to boil more or less violently for about fifteen minutes. After this fifteen to thirty minutes are allowed to elapse, and any excess of slag beyond what is required to cover the metal in the casting ladle is removed, when the

FIG. 1.

SECTION AT C.C.

FIG. 2.

heat is reached. In three-and-a-half to six hours, the time being dependent on the proportion of pig to scrap, the whole charge will be melted, more slag can be taken off if required, some lime added if the slag is very fluid, and ore with the lime of the proportion of pig to scrap is high. When the boiling has ceased, and after the bulk of fluid metal has been well stirred, the metal may be sampled. The sample being satisfactory, the pasty slag

metal is ready for adding spiegel or ferro-manganese, and tapping. The addition of hematite pig causes a thorough agitation of the bath far beyond what can be done by stirring, and every analysis made proves a further removal of phosphorus by the addition. Occasionally, however, this after boil causes failure of parts of the hearth. Attempts to secure the quality of steel aimed at without adding pig at the end of the purifica-

tion were made, but the results were uncertain and irregular. In only one instance has the author obtained evidence of re-phosphorisation on adding the ferromanganese after adding hematite pig. In this case the sample showed 0.104 per cent. of phosphorus, while the finished steel showed 0.122 per cent. In other cases

and more free from adhering sand than the cheaper hot-blast irons, much of the success obtained must be credited to the principal raw material used. To remedy certain defects of the experimental furnace, the author has designed the furnace shown—Figs. 5 to 9—in which the gas- and air-passages are carried up outside the walls of

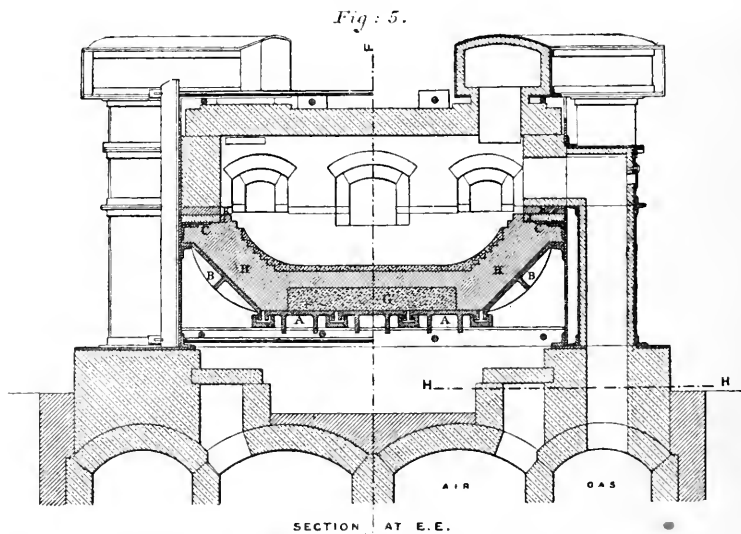

Fig. 4.

SECTION AT D.D.

where the two respective samples were tested for phosphorus, the reduction per cent. averaged 0.016, and varied from 0.008 to 0.025 less phosphorus in the steel than the trial samples contained. Highly satisfactory results were obtained; but it may be remarked that Farnley Best Yorkshire cold-blast pig has been the only phosphoric pig used; and being so low in silicon and sulphur, regular in quality,

the furnace, an arrangement patented by Haekney and Wailles. Three doors for charging and repairing, and two slag spouts are provided on the opposite side to the tap-hole for the metal, and two sight-holes LL. Owing to the very soft quality of the steel produced, the heat required is nearly as great as Sheffield silica-bricks are able to withstand; so long as the slag can be kept clear

of the magnesia and bauxite bricks they have been satisfactory, and, but for their great cost, magnesia bricks would doubtless be much better than silica bricks for the faces of the ports. The waste is not excessive; taking the more recent work, without charging or crediting skulls and pit-scrap, the results for the 106 casts are as

Numerous mechanical tests are given, the average breaking weight being 24.76 tons per square inch, with a minimum of 22.29, and a maximum of 26.68; average elongation on eight inches being 30.62 per cent., with a minimum of 25.0, and a maximum of 37.5. The order of removal of phosphorus is different from

FIG. 7.

Fig: 8

follows:—Farnley pig, 90.4 tons; hematite pig, 9.675; iron and steel scrap, 130.15; ferro-manganese, 4.73—total, say 235 tons charged. The total weight produced, of ingots and spare metal, is 219.3 tons, or about 93 per cent. of the raw materials. About 9cwt. of raw dolomite per ton of ingots has been used for repairs of the furnace, as deduced from the work done during the year.

that in the Bessemer converter. In the latter process the phosphorus is not eliminated to any great extent until the carbon and silicon have almost disappeared; hence so little as 1.974 per cent. of phosphoric acid in the final slag was not expected. Another sample of slag, taken after the pig was fluid, but before the scraps were melted, was, however, found to contain 5.087 per cent.

of phosphoric acid. Samples of metal taken when the whole charge was melted, and before boiling commenced, have always been found to contain less phosphorus than the charge was known to contain, showing that the elimination of phosphorus commences in the early stages. Sulphur does not appear to be eliminated during the process. A sample of deposit from the gas-regenerator contained 4.741 per cent. of phosphoric acid; and another

sample from the air-regenerator contained 2.995 per cent.; thus indicating that some of the phosphorus leaves the furnace otherwise than in the slags. The analyses were made by J. O. Arnold. The phosphorus was precipitated boiling by molybdate solution, and reprecipitated by magnesium mixture, giving results higher than are obtained by the molybdate method.—J. T.

#### Variation in the Elasticity of Iron and Steel. Chem. Centr. 16, 574—575.

It is a well-known fact that iron obtained by puddling and welding is not homogeneous throughout, and it has been shown that blocks of Bessemer steel have towards the centre a larger percentage of carbon, silicon, sulphur, phosphorus and manganese. In many works the homogeneity of the steel is tested by the change of colour produced by change of temperature. Kerpely has shown that a cast steel obtained by melting a cementation steel of greater hardness than the standard can only serve for this test, since the stirring of the molten mass by itself produces very little effect. By heating masses of heterogeneous iron and steel similar changes take place as in the cementation process, and in the method for producing tempered steel by heating cast iron with iron oxide. A kind of internal cementation goes on which, if sufficient time be allowed, must produce a metal of greater chemical uniformity. Fibrous iron, which has been exposed to a high temperature for some time, becomes more brittle but less hard, and acquires a crystalline fracture.—S. R.

#### Production of Lead, Silver, and Zinc in Germany during the Year 1884. Chem. Centr. 16, 589—590.

The total production of lead throughout the world is estimated as being between 450,000 and 500,000 tons annually. In 1884, Spain contributed 90,000 tons, and North America 139,897 tons.

#### Process for Electrolytic Extraction of Copper from its Ores. Eugenio Marchese, Genoa. Eng. Pat. 12,725, September 23, 1884.

A PORTION of the ore is smelted so as to form a matt, consisting generally of copper, iron and sulphur. This is cast into plates, to be employed as the anodes in the electrolytic baths, plates of copper being used as cathodes. Another portion of ore is roasted and lixiviated, sulphuric acid being added to dissolve the oxides. The resulting solution of the sulphates of copper and iron is charged into the electrolytic baths, where it is decomposed by the current. Metallic copper is deposited on the cathodes, and the sulphides of the anodes are dissolved. The electric current is obtained largely by the oxidation of the iron in the anodes. The spent anodes are used for the production of sulphur and sulphuric acid, and the sulphate of iron in the spent liquor is crystallised.—S. Y.

#### Process for the Recovery of Tin from Tinplate Scrap and other Materials containing Tin, such as Oxidised Metal and Residues. Herbert John Haddan, Strand, Westminster. From Alfred Lambotte, Brussels. Eng. Pat. 14,672, November 6, 1884.

THE matter to be treated is subjected in suitable chambers to the action of chlorine gas, largely diluted with air, and heated to a temperature above the boiling point of stannic chloride. The chloride formed is suitably condensed, either by injecting steam into the gases as they leave these chambers, and collecting the crystals in condensation chambers (the dry gases may, if preferred, be led into the condensation chambers, the walls of which must then be kept moist), or by absorbing it in a solution of stannic chloride. The evaporation of the concentrated solution may be conducted without risk of decomposition by passing through it a current of warm air. Dilute chlorine, yielded in certain chemical processes, is available for this method of treatment.

—W. G. M.

**A Process for Producing Aluminium from Chloride of Aluminium** ( $Al_2Cl_6$ ). Hector von Groussilliers, Springe, Hanover. Eng. Pat. 7855, June 29, 1885.

IN order to avoid the difficulties ordinarily met with in the use of aluminium-sodium-chloride to obtain metallic aluminium, the patentee raises the volatilising point of the simple chloride by performing the reduction, either chemical or electrolytic, under pressure in a strong hermetically closed vessel, lined with clay or magnesite, and provided with a safety valve.—W. G. M.

**Improvements in Metallurgical Furnaces.** John Thomson King, Liverpool. From Samuel Thomas Owens, Pittsburg, U.S. Eng. Pat. 8478, July 14, 1885.

THIS is a form of regenerative furnace, in which the heated products of combustion pass continuously in the same direction through clay pipes, supported at the joints, and laid in a chamber beneath the furnace. The air to be employed in combustion is heated by passing between these pipes into a long arched space above them; thence it flows to the fire bridge. The gas is supplied through a series of nozzles placed on a level with the top of the bridge; it may be warm, as supplied direct from the producer, or be heated by traversing pipes placed in the air space above the flue pipes already described.—W. G. M.

**Improvements in Apparatus for Refining Copper and other Metallic Matters by Electrolytic and Chemical Actions.** W. Wood and M. H. Hurrell, London. Eng. Pat. 8661, July 17, 1885.

IMPROVEMENTS in apparatus for refining by electrolytic and chemical action copper and other matters of metals, which are with difficulty, if at all, separated by the process of fusion. In a main tank, porous cells, containing the matte cast in the form of anodes, together with the cathode plates, are arranged so as to secure the upward and downward flow over their surfaces of the electrolytic solutions. There is an elevated supply tank, with distributing pipes, for supplying the solution to the main tank, and an arrangement by means of which the weak solution from the main tank is conveyed to the porous cells, and the strong solution away from the lower part of the porous cells. A chemical precipitating tank, fitted with plates, is also arranged so as to secure an upward and downward flow of the solution, and to return it from the precipitating tank to the elevated tank. A pump for raising the solution to the elevated supply tank is set in motion and stopped by the action of the return solution.—T.

**Improvements in and Relating to the Purity of Iron and Steel.** William Robert Lake, London. From William Henry Purdy, Brooklyn, U.S. Eng. Pat. 8819, July 21, 1885.

THE interior of the melting vessel is lined to the depth of one quarter of an inch (or the metal itself may be painted before fusion) with a mixture of minium (1lb.), litharge (1lb.), cinnabar (1lb.), and moulding sand or loam (3lb.), with one gallon of water. The basic nature of this mixture causes it to exert a purifying action on the melted iron; whilst the excess of the oxygen of the minium removes a portion of the carbon.—W. G. M.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

**Adulteration of Olive Oil.** Arch. Pharm. 3, 23, 280.

THE various oils commonly employed for the adulteration of olive oil may be detected as follows:—

**Linseed Oil.**—2cc. nitric acid is mixed with 5cc. of the sample, and a piece of bright copper wire introduced into the mixture. If after half-an-hour the wire has acquired a rose colour the olive oil contained linseed oil as an adulterant.

**Cotton-seed Oil.**—The olive oil is mixed with an equal quantity of nitric acid (40° B.). A brown colouration indicates the presence of cotton-seed oil.

**Sesame Oil.**—An equal quantity of hydrochloric acid (23° B.) is added, and a fragment of cane-sugar dissolved in the mixture. If after shaking and standing a red colour is developed, sesame oil is present.

**Colza Oil.**—10grm. of the oil is saponified with an alcoholic solution of caustic potash (free from sulphur); a darkening in colour shows that colza oil has been added.

**Earth-nut Oil.**—The oil is saponified with alcoholic potash solution, and the soap when separated is warmed to remove the alcohol. It is then decomposed with hydrochloric acid, and the liberated fatty acids dissolved in boiling alcohol. If the oil has been adulterated, arachidic acid will now separate out. It can be recognised by its mother of pearl lustre.—S. R.

**Determination of the Sp. Gr. of Butter and Tallow at 100°** Wolckenhaar. Rep. Anal. Chem. 5, 236.

THE author has determined the sp. gr. of these fats by means of an areometer, and has compared the indications of the instrument with the numbers obtained by weighing a standard sinker, immersed in molten fat. The results were not concordant, and established a serious but nearly constant discrepancy between the true sp. gr. and the areometer readings; this is shown by the following numbers (mean of six determinations, probable error < 0.003):—

	By Areometer. sp. gr.	By the Balance. sp. gr.
Butter .....	0.865	0.9025
Tallow .....	0.860	0.8938

—C. F. C.

**Chemical Action of Soaps.** Professor Rotondi, of the Royal Industrial Museum of Turin. Chem. Rev. 14, 228.

THE author rejects the theory of Berzelius, that the usefulness of soaps depends upon the facility with which neutral soaps decompose on solution into acid soaps and free alkali, and also that of Persoz, who assumes neutral soaps to be soluble in hot water without decomposition, but to be resolved in cold water into acid and basic soaps—the latter dissolving fatty substances by saponification. These hypotheses do not explain why hot soap solutions are more active than cold ones. The following conclusions were arrived at by the author from experiments upon carefully purified Marseilles soap. Neutral soaps on solution are decomposed into basic and acid soaps, the latter are insoluble in cold, and only slightly soluble in hot water; they are not dialysable, and so are thus separable from the former, which are readily so. The neutral soaps, though thus decomposed, lose neither free nor carbonated alkali. Basic soaps are completely soluble in cold and hot water, and are entirely precipitated by sodium chloride without loss of alkali; their solutions dissolve acid soaps on heating, but become turbid on cooling. They emulsify fatty bodies readily, but no saponification of the latter takes place; neutral soaps possess this property to a smaller extent, acid soaps scarcely at all. Carbonic acid produces in cold solutions of basic soaps insoluble compounds, which, however, disappear on heating, hence waters rich in carbonic acid are not suited for industrial operations with soap. The above explains the greater efficiency of hot soap solutions, and bears importantly upon the manufacture and industrial uses of soap, inasmuch as different results are often observed in the use of soaps made from the same materials (and containing no free alkali), due to their containing variable amounts of acid and basic soaps. The author considers that soaps should consist as nearly as possible of neutral compounds, citing instances of danger attendant upon the presence of an excess of basic soap—e.g., in the boiling of silks. These are facts to be borne in mind in the operations of soap-boiling, as well as in soap analysis when it is desired to ascertain the fitness of a sample for a given purpose.—E. E. B.

*A New or Improved Method of, and Apparatus for the Emulsion of two Substances of Dissimilar Specific Gravity.* E. G. Brewer, of London. From Burnmeister and Wain's Maskin and Skibshyggeri, Copenhagen. Eng. Pat. 11,907, September 2, 1884.

This invention consists in the employment of centrifugal-power machines for the production of the emulsion of some fatty substance in milk; this may be effected either with or without the simultaneous separation of cream from the milk. The fat-delivery pipes are usually led from a small reservoir arranged on the centrifugal spindle, and when the latter rotates, the fat is driven in fine streams into the milk. In some cases, however, the fat-delivery tube is stationary, and adjustable in the cover of the centrifugal reservoir, in which case its opening is more or less bent. Drawings of these various openings are given. The claim is very elaborate, and is summed up in 13 heads.—W. L. C.

*Improvement in the Manufacture of Soap.* Clem. Harrison, East Dulwich. Eng. Pat. 12,841, September 26, 1884.

To increase the detergent qualities of soap, turps, ammonia, and pearlsh, in suitable proportions (none are given) with or without the addition of methylated spirit, are incorporated either with soap, or with fats and oils prior to their saponification.—W. L. C.

*A New or Improved Process for Obtaining useful Products from the Yolk or Grease of Wool.* W. H. Beck. From C. Viollette, of Lille, and A. Vinchon, of Roubaix. Eng. Pat. 13,815, October 18, 1884.

THE perfectly dried yolk is heated in a boiler to 250° or 300° (whether C. or F. is not stated) for some hours with one-fourth its weight of solid caustic soda, the mass being agitated by mechanical stirrers. The free fatty acids are thus saponified, and the neutral ethers are decomposed; the alcohols also are transformed into their corresponding acids, for example ceryl alcohol into cerotic acid. When the reactions are completed the mass is treated with three or four times its weight of boiling water, after which the soda solution thus formed is concentrated and calcined, while the soaps are decomposed with a mineral acid, and the resulting fatty acids,

*Improvements in the Process of Manufacturing Railway Axle, or other Grease, and in Plant or Apparatus applicable therefor.* M. W. Hydes and J. H. Williams. Eng. Pat., December 16, 1884.

THIS contains solely the description of a jacketed pan, graduated to show the contents at a given height, fitted with superheated and ordinary steam, run-off cocks, reservoirs, etc. To render control of the operations easy, the cocks of the various pipes are all brought to one dial plate. A drawing is given, but no process of manufacture is described.—W. L. C.

*An Improved Compound for Cleansing Wool and other Fibres, Cloth, and other Fabrics.* James Hanford, Leeds. Eng. Pat. 7004, June 9, 1885.

LARD, resin, and American potash are incorporated and allowed to stand for some days, after which silicate of soda, soda-ash, soft soap, Irish moss, and farina, are added; the whole is boiled for two hours, and after straining and cooling is ready for use. The proportions of ingredients necessary for 25cwt. of the compound are named.—W. L. C.

### XIII.—TANNING, LEATHER, GLUE, AND SIZE.

*A Blackening for Leather Articles.* Chem. Centr.-Blatt. 16, 543.

THE following receipt gives a black which will take a good polish, and can be used for any kind of leather:—To 3lb. of boiling water are added ½ lb. of white wax, 1oz. transparent gelatine, 2oz. gum senegal, 1½oz. white soap, and 2oz. brown sugar; when the mixture is cold 2½oz. of alcohol and 3oz. of Frankfort black are added. It is applied to the leather with a soft brush, and when dry the leather is rubbed with pumice stone and finally polished.—S. R.

### XIV.—AGRICULTURE, MANURES, Etc.

*On the Yield of Alkaloids from Different Species and Varieties of Lupin.* E. Hiller (Landwirthsch. Vers.-Stat. 31, 336–341).

THE following table contains the results of analyses by the author, and by E. Tauber (*Ibid.* 29, 451):—

—S. Y.

which are specially waxy in character, are distilled in superheated steam. Soda-lime, or potash-lime, may be substituted for the caustic soda. It is claimed that the solid fatty acids are more than 50 per cent. of the primary material employed, and that the process resolves satisfactorily the question of the purification of wash waters from wool.—W. L. C.

*Soils and Peats from the Baltic Region.* Prof. G. Thoms, Baltisch. Wochenschr. 1883-4, Bied. Centr. 13, 1884, 410.

THIRTY-NINE samples (of loam, marl, and other soils) contained proportions of phosphoric acid ranging from

0.02 per cent. to 0.19 per cent., the mean being 0.0763 per cent. Thirty-six samples of moorland soil were found to contain the following proportions of mineral matter, nitrogen, potash, and phosphoric acid:—

consists of a peculiar modification of cellular tissue, scarcely to be distinguished from pure cellulose. Other examples of this compact horny structure are to be found in the date-stone and the coffee-berry.—E. G. C.

*A New Cattle Food.* H. Gilbert. Bied. Centr. **13**, 1884.

THIS article was sold under the names of "strength food," and "palm-nut meal," and it was found by the author to consist of 12 per cent. of common salt, and 88 per cent. of vegetable ivory turnings. These were a waste product from the manufacture of buttons, and their nutritive value was very trifling, because of their horny character. The results of the analysis were as follows:—

		Control- analysis of some v. l. turnings.
Fat .....	1.05	1.02
Proteids .....	4.19	4.81
Ash (including 11.51% of salt) .....	13.61	1.46
Woody fibre .....	10.33	13.61
Water .....	9.20	10.50
Non-nitrogenous extractive matter .....	61.37	68.60
	100.00	100.00

This cattle food was not pulverulent, like palm-nut meal, but contained little white and brown particles, which could be separated from the salt by treatment with water. The nuts known as vegetable ivory come from a kind of palm (*Phytelphas macrocarpa*), and are imported from Columbia and Ecuador. Dr. J. Moeller states that the horny matter of which these nuts are composed

contains from 2.1 to 3.0 per cent. of nitrogen (calculated on the dry substance), while 1,000 parts of the waste water contain from 12½ to 15½ parts of solid matter, of which from 3.2 to 4.7 parts are lost on ignition, together with 0.2 part of ammonia. This waste water is allowed to run into pits, but no indications of contamination of the water of neighbouring wells have yet been observed.

—E. G. C.

*The Manuring of Hops.* E. Pott. Bied. Centr. **13**, 412.

THE author considers that the manures commonly used, such as stable-manure, refuse from latrines, etc., have a tendency to increase the quantity of hops yielded, at the expense of their quality. Hops should not be over-manured, and manures rich in nitrogen should be especially avoided. From 3 to 6 kilos. of bone meal, with 1½ to 2 kilos. of Chili saltpetre, to the square metre, in soils poor in phosphoric acid, or from 6 to 15 kilos. of crude potassium chloride, with or without Chili saltpetre, on land poor in potash, would furnish satisfactory results.—E. G. C.

*Bavarian Peat.* Th. Schreiber. Bied. Centr. **13**, 418.

THE results of analyses of 27 samples of Bavarian peat are given in this paper, the percentage proportions of fibre, dust, mineral and organic matter, and nitrogen, being stated. It appears that Bavarian peat is richer in nitrogen than North German peat.—E. G. C.

*On the Absorption of Nitrogen by the Leguminosae.*  
Bontellau. Bied. Centr. 13, 420.

A PLOT of land, previously a vineyard, was manured with 800 to 900 kilos. of superphosphate, and sown with oats in the autumn. In the following spring, the field received a top-dressing of 150 kilos. of Chili saltpetre, and was then sown with lucerne and esparsette, among the grain: 45 hectolitres of the latter were reaped in August. In the next autumn the plot was treated with 800 to 900 kilos. of a manure containing 14 per cent. of potash and 6 per cent. of phosphoric acid, which was exclusively employed during the following year. The yield of dry fodder from the three annual reapings amounted to 14-15,000 kilos. From whence did these considerable crops derive their nitrogen? For, the author observes, the one manuring with Chili saltpetre was absorbed by the crop of grain, other experiments having shown that the soil was not in a condition, without manuring with nitrogen, to yield good grain crops; and yet the leguminosae flourished well. Another field was treated with 35,000 kilos. of stable-manure, and then planted, one-third with potatoes, one-third with maize, and one-third with vetches. Next year the whole field was sown with wheat, the portion where potatoes had grown yielded 30 hectolitres, the plot previously covered with maize yielded 28 hectolitres, and the part where the vetches had been furnished 35 hectolitres. The vetches contained more nitrogen than the maize, and yet the wheat crop was more abundant after the vetches than after the maize.—E. G. C.

*On the Separation of Oxygen in the Leaves of the Crassulaceae.* Adolph Mayer. Bied. Centr. 13, 422.

SOME previous investigations of the author appeared to indicate that leaves of the crassulaceae, exposed to the light in an atmosphere free from carbonic anhydride, separate oxygen gas, and lose their acidity. This acidity was considered by the author to be due to a modification of malic acid, called by him iso-malic acid, and which he thought might be converted, by a process of reduction, into a carbohydrate. The results of further experiments have served to support the accuracy of these conclusions, an increase in saccharine and starchy matter having been observed by A. Mayer in the leaves after exposure.—E. G. C.

*On some Points in the Composition of Soils, with Results illustrating the Sources of Fertility of Manitoba Prairie Soils.* J. B. Lawes and J. H. Gilbert. J. Chem. Soc. (Trans.) 1885, 380-422.

THE present communication is a continuation of a previous paper relating to the sources of nitrogen of our crops (J. Chem. Soc. (abstr.), 1884, 682-691), wherein are set forth and discussed the results of the determinations of nitrogen in various experimental crops, and in the upper layers of the soil upon which they were cultivated. In that paper the authors show, amongst other things, that the annual yield of nitrogen is least in cereals, greater in roots, and still greater in leguminous crops, whilst with rotation, when roots and leguminous crops are interplanted with cereals, the yield is greater than with cereals continuously grown; but whenever the same crop is grown year after year on the same land without manure, or with mineral (non-nitrogenous) manure only, in all cases, and with all crops on arable land, there is a great decrease in the annual yield of nitrogen, and in most cases this is accompanied by a simultaneous decline in the quantity of nitrogen in the surface soil. This is especially evident in cereal and root crops; in fact, almost all their nitrogen may be traced to the deficit in the soil. With leguminosae grown occasionally on arable soil, however, the reverse is sometimes the case, and the surface soil is found richer in nitrogen after, than it was before the crop was grown; hence, cereals thrive well on land after clover. But experiments with leguminosae grown continuously on the same garden soil, indicate that they follow the above rule, and each successive year the nitrogen, both in soil and in crop, becomes less; in fact, almost all the nitrogen in the crop can be accounted for by the loss of

nitrogen in the first eighteen inches of soil, and the small quantity supplied in rain, etc. Mixed herbage on permanent grass land yields more nitrogen per acre per annum when manured with mineral (non-nitrogenous) manure, than when it receives no manure, and this increase is found to be more than counterbalanced by a loss of nitrogen in the soil. Strong, deeply-rooted plants (*melilotus leucantha*) have yielded large quantities of nitrogen, when similar but weaker plants (*trifolium repens*) have failed to thrive, the soil was found much less moist in the former than in the latter case. Taking these facts into consideration, coupled with the fact, as the authors point out, that the quantity of combined nitrogen supplied from the atmosphere in rain, dew, and all other forms is quite inadequate for the requirements of plants; and as, moreover, the balance of experimental evidence is against the supposition that plants assimilate free nitrogen from the atmosphere, they conclude that the store of nitrogen in the soil is the source of at least most of the nitrogen in the plants. Whilst in this and other papers it is shown that much of the nitrogen derived from the soil is taken up as nitrate.

These investigations have now been extended to other soils and to sub-soils; the above results relating principally to surface soils. Towards the end of July, 1883, after the crops were removed, soil samples were taken to the depth of twelve times nine inches, from plots of common vetch (*vicia sativa*) from plots of white clover (*trifolium repens*), and from wheat and fallow land, which had been fallow since the previous harvest. These plots were all in the same field, quite close together. A fairly luxuriant crop has been taken off the vetch plots, but there was no plant at all on the white clover plot. The results of the determination of nitrogen as nitric acid in the various samples are tabulated below, the figures being pounds per acre:—

Depth.	Unmanured Wheat and Fallow Land	Mineral (non-nitrogenous) Manure.		
		<i>Trifolium repens</i> Plot 4.	<i>Vicia sativa</i> .	
			Plot 4.	Plot 6.
Inches. 1-9	19'85	30'90	12'16	10'22
10-13	8'05	27'73	4'11	2'72
19-27	2'47	8'41	1'37	1'08

100-103	1'81	9'51	5'32	6'46
1-103	52'10	115'70	61'21	54'72

Comparing the wheat-land fallow plot with the *trifolium repens* plot, which was practically fallow, there is a remarkable difference in the amounts of nitrogen as nitric acid. Looking to the previous history, the one had grown wheat alternately with fallow for more than thirty years, and the other, during the same period, had grown six graminaceous crops, been frequently fallow, but had been sown twelve times with red clover, and during the immediately preceding six years four times with white clover. Thus, irrespective of the, for the present purpose, unimportant dressing with mineral manure in the one case and not in the other, the whole difference had been the introduction of leguminous crops on the one, and not on the other, with the result that there is nearly three times as much nitrogen

as nitric acid found in that soil, to the depth of 108 inches, as in the other to a corresponding depth. It is hence inferred that nitrification is more active under the influence of leguminous than of graminaceous growth and crop residue. Sub-soils have been found to contain no nitrifying organisms (Warrington, *J. Chem. Soc. (Trans.)*, 1884, 637); but from other experiments the authors have shown that the nitrogen of sub-soil, when subjected to suitable conditions, is capable of nitrification. The beneficial influence of leguminous growth is shown at a great depth, with strong, deep-rooted *melilotus lanceolatus*, for the channels made by its roots and by worms, would allow the nitrifying organism to pass down along with other substances, whilst owing to the large quantity of water drawn up (see above), air, water, etc., must necessarily pass down. Therefore, upon this supposition the greater the root development the greater would be the amount of nitric acid formed, and of nitrogen rendered available in this form to the plant from the sub-soil. If established this would go far to explain the large amounts of nitrogen yielded by these deep-rooted leguminous crops over a given area; and would, moreover, account for the fact that where a crop of a certain root-range has failed, having exhausted its store of suitable nitrogenous matter, a plant of another root-range thrives. Thus *melilotus lanceolatus*, *vicia sativa*, and *medicago sativa* succeeded where red clover failed, and clover thrives where beans had failed. Hence, in explanation, it is suggested, supposing a healthy leguminous plant is established, whether its growth, excretions, and residue do not exert a favourable influence on the development of the nitrifying organism, at first in the rich upper, subsequently in the poorer lower layers of the soil, and thus gradually render the organic nitrogen of the soil and sub-soil available for the requirements of growth; consequently there is a large crop, and a large crop residue, which enriches the surface soil. But this explanation requires proof. With regard to the assimilation of nitrogen in organic combination from the soil, by green-leaved plants, it is pointed out that there is no direct evidence in favour of such a view, whilst there are physiological considerations which seem to be against it. On the other hand the assimilation of nitric acid is evident from the above table, when the quantities of nitrogen as nitric acid found in the *trifolium repens* plot, where there was no plant to take it up, is compared with the nitrogen as nitric acid in the *vicia* plots, where there was plenty of growth to utilise the nitric acid formed; so great is the difference that the nitrogen deficit in the *vicia* plots is sufficient to account for a large proportion of the nitrogen contained in the *vetch* crop. Other experiments are described, which likewise bear indirectly on this point, and are accordant, but which more directly illustrate the loss of nitrogen, which may result from leaving land fallow during a wet season; it is hence deemed advisable to keep land covered with a crop to take up the nitrate as it is produced. In concluding this part of the paper the authors regard as established that a considerable quantity of the nitrogen of plants is derived from the stores in the soil, and that much, and in some cases the whole, of this nitrogen is taken up as nitrate.

From the above suggestions it would seem that a soil containing sufficient available mineral constituents, and a large proportion of nitrogen, which is readily nitrified, may be regarded as fertile; and, therefore, virgin prairie soils should fulfil these conditions. To test this point the following investigations were made with Manitoba prairie soils, which are not deficient in mineral matter. Surface soils, from Portage la Prairie, which had been under cultivation several years, from the Saskatchewan district also under cultivation some time, and from Fort Ellice, virgin soil, contained respectively 0.2471, 0.3027, 0.2500 per cent. of nitrogen, and are twice as rich in nitrogen as the average arable soil in Great Britain, and perhaps about as rich as the average of the surface soils of permanent pasture land. Four other Manitoba soils were more thoroughly examined, and experiments were conducted to ascertain the susceptibility to nitrification of the nitrogen in them. The soils were (1) from Niverville, about 44 miles west of Winnipeg; had been broken

from the prairie five or six years, and had grown five crops of cereals. (2) From Brandon, about 132 miles west of Winnipeg; had been broken up in 1882, back set in 1883, and grew 25 bushels of wheat per acre that year. (3) From Selkirk, which had never been broken up. (4) From Winnipeg; broken up about five years; had been thoroughly cultivated, and manured, and had grown good crops of potatoes. There were four samples of each of these soils investigated, representing the first, second, third and fourth 12 inches from the surface. For the nitrification experiments the samples were extracted with water on a vacuum pump, the nitrogen as nitric acid estimated in the extract, and the extracted soils were broken up, exposed to the air in shallow vessels in a moist condition, and at a suitable temperature, being covered loosely with glass plates to protect them from dust; at the end of periods of about twenty-eight days or more the samples were again extracted, the nitrogen as nitric acid determined in the extract, and the extracted masses exposed as before. After the fourth extraction, potassium phosphate, magnesium sulphate and calcium carbonate were added to the samples to replace the mineral matter removed by the repeated extractions, as it might be that the reduction of nitrification noticed at that period was due to the want of mineral matters necessary for the development of the nitrifying organism; whilst after the seventh period some of the less active samples were seeded with 0.1 gm. of rich garden mould. The results are given in table on p. 606. The first column of results shows the total quantity of nitrogen, whilst the following columns indicate the condition of the nitrogen, or its nitrifiability and usefulness to plant life. When it is remembered that the percentage of nitrogen in the dry arable soils at Rothamsted, in the first 9 inches, seldom exceeds 0.14 or 0.15, and is sometimes as low as 0.10; in the second 9 inches it ranges from 0.07 to slightly more than 0.08; in third 9 inches from below 0.06 to about 0.07, whilst in the lower depths it is still less, it will appear that these Manitoba soils are undoubtedly very fertile, and may be compared to the surface soil of old pasture land at Rothamsted, which contains from 0.25 to 0.30 per cent. of nitrogen. The second column of results relates to the amount of nitrogen as nitric acid found in the samples, at the commencement of the experiments, and are naturally irregular, owing to the different conditions of the samples, as to moisture, etc. The third and subsequent columns of results show the progress of nitrification. It will be seen that in each set of soils the nitrification is greater in the richer surface soils than it is in the poorer sub-soils, and generally, but not uniformly, greater in the second than in the third, and in the third than in the fourth depth of 12 inches. When the activity began to diminish at the fourth period, the mineral matter was added to all the samples, but without improving matters, owing at first to the quantity added being too great; but even in a subsequent extraction (7th period) the production of nitric nitrogen was still very small, and therefore the garden soil was added as already stated, with the result indicated in the last column, where the amount of nitrogen nitrified shows a considerable increase over that of the seventh period. The percentage of the original nitrogen nitrified throughout the experiment up to the end of the eighth period, was, in each case, as follows:—

	Niverville.	Brandon.	Selkirk.	Winnipeg.
1st depth.....	3.21*	4.78	3.77	6.42
2nd ".....	1.26	1.61*	4.48	3.55
3rd ".....	0.51	2.07	4.00	4.85
4th ".....	1.00	1.22	0.77	2.78

It is remarked that the conditions of these experiments cannot be compared with those of the soils in their actual conditions of aeration, moisture and temperature; nevertheless, the results are very important, showing, if the sub-soils are really pure, that the nitrogenous matter of sub-soils is liable to nitrification when the conditions are suitable for such a change to take place. This susceptibility of the nitrogen to oxidation may be a source of loss, if there is no crop to take up the nitrates

\* Too low.

when formed. In spite of the great richness of these soils, they do not produce as much wheat per acre per annum as is obtained in Great Britain; this is owing, in part, to unfavourable climatic influences, and short seasons of growth, but more largely to scarcity of labour, and consequently bad cultivation. A table is given comparing the percentage of nitrogen and carbon in various soils of known history—Rothamsted arable and grass soils, arable soils in Great Britain, United States (Illinois) and Canadian prairie soils, and rich Russian soils, from which it seems that the rich virgin soils, or permanent

nitrate is used than when sodium nitrate is employed. The author, having repeated these experiments has not remarked this difference, and has arrived at the conclusion that nitrate of sodium in the soil is changed into potassium nitrate, and that only the latter is assimilated by the plants. A difference between the action of the two salts is only observed in those soils in which there is a deficiency of potassium, and in which, therefore, conversion of the sodium salt into the potassium salt cannot take place. An instance of this conversion is furnished by the author, who states that

Results marked thus \* are too low. Those marked thus † are after 25 days, and those in brackets ( ) are 23 days after adding the garden soil.

pasture surface soils, contain a high percentage of nitrogen and of carbon, and a high relation of carbon to nitrogen. An arable soil which has long been under cultivation, is much poorer in these respects; whilst an agriculturally-exhausted arable soil shows very low percentages of nitrogen and carbon, and a very low relation of carbon to nitrogen. A fertile soil may then be defined in the words of the authors, as one "which has accumulated within it the residue of ages of previous vegetation, and that it becomes unfertile as this residue is exhausted." The paper terminates with a copious summary and the conclusions of the authors.—D. A. L.

*On the Influence of "Nitrate of Soda" and ordinary Salt-petre on Potatoes.* P. Dehcrain. *Bied. Centr.* 13, 424.

ACCORDING to experiments made by Elder, at Gingenödt, a better yield of potatoes is obtained when potassium

although the ash of some beans, which, before incineration, had been immersed in solutions of common salt contained 11.2 per cent. of chlorine, no sodium, but on the contrary, abundance of potassium was found.—E. G. C.

## XV.—SUGAR, GUMS, STARCHES, Etc.

*Microbes in the Filters of Sugar Refineries.* T. Mendes. *Ztschr. d. Ver. f. Rüben. Zuckerind.* 22, 396—406.

THE sugar-water from the refinery filter occasionally becomes turbid and of a pale yellow-white colour. A sample of this water had a smell of sour milk, became acid, and gave a precipitate with ammonia of calcium phosphate and carbonate, and eventually turned black. From a microscopic examination of the weak syrup and sugar-water from several sugar factories at

different periods the author finds that in all cases the turbidity is due to the same microbe, which is recognised by its bacillus-like form. The germs of this bacillus do not lose their vitality even at the temperature of boiling water. The original paper is accompanied with figures.

—S. R.

*On Some Reactions of Saccharin.* P. Herrmann and B. Tollens. Ber. **18**, 1333.

It has been shown by Tollens and others that true carbohydrates when boiled with dilute mineral acids yield levulinic or  $\beta$ -acetopropionic acid, while other substances of similar composition, such as methylenitone and inositol, do not yield this acid, and Kent and Tollens have suggested that the production of levulinic acid from a vegetable matter is a proof that it is a carbohydrate.

Saccharin, which has the same composition as starch, but a different constitution, was boiled with hydrochloric acid for twenty hours, but the greater part of the saccharine remained unaltered, and the presence of levulinic acid could not be recognised. The substance is therefore not a true carbohydrate.

It has been suggested by Kiliani and by Liebermann and Scheibler that saccharin is the lactone of saccharic acid, the latter being a substitution product of lactic acid.

A concentrated solution of saccharin when treated with potassium iodide solution and sodium hydrate yielded considerable quantities of iodoform, hence it is almost certain that the substance contains a methyl group.

Lactic acid was also prepared from saccharin by heating the substance with an aqueous solution of potassium hydrate, and allowing the temperature to rise gradually to 220°. (At a higher temperature lactic acid is decomposed with formation of oxalic acid.) The authors conclude that saccharin is an intermediate product between dextrose and lactic acid, and that it is the lactone of a lactic acid in which hydrogen is replaced by the group —CH.OH—CH.OH—CH<sub>2</sub>.OH.—S. Y.

*On the Waste Waters from Sugar Factories.* W. Demel. Bied. Centr. **13**, 361.

THE author has analysed the waste waters from various sugar works. One series of results obtained by him is embodied in the following table :—

thick sediment and offensive odour. The author concludes by pointing out the great objections attaching to the pollution of river-water with such obnoxious fluids as these.—E. G. C.

*On the Separation of Raffinose from the Molasses of the Sugar-beet.* C. Scheibler. Ber. **18**, 1409.

FIFTEEN years ago the author noticed the occasional occurrence of sugars the complete analysis of which yielded numbers greater than 100. Such sugars, therefore, appear to contain no non-saccharine organic substances. The author suspected the presence of a body of high rotary power and of dextrin.

It is only, however, of late years since the introduction of the method of obtaining sugar from molasses by means of strontium hydrate that the question has received much attention, and that the observation of analyses of sugar solutions giving numbers greater than 100 has become common, that from such solutions the sugar has been observed to crystallise in peculiar elongated prismatic forms, which are, however, in reality only distorted forms of ordinary sugar crystals.

In 1882 Reichardt and Bittmann again concluded that a body of high rotary power must be present, and quite recently Tollens (Ber. **18**, 26) suggested that this body was the raffinose discovered by Loiseau, probably identical with gossypose prepared from cotton-seed cake. Raffinose was evidently obtained accidentally by Loiseau, and no direct method of preparation has yet been described. The author now shows how it may be prepared in quantity. The materials employed were the elongated crystals, the after product and the syrup obtained by Stollan's method from beet-root molasses. The crystalline products were dissolved in hot water, and to one molecule of sugar (calculated by rotary power) one molecule of strontium oxide was added. After cooling, a little monostrontium saccharate was added to induce crystallisation, and after some hours the crystallised product was separated by filtration with the pump. The mother-liquor, which contained seventy-five per cent. less sugar than the original solution, was treated with excess of strontium oxide, whereby the remaining sugar and the raffinose were both precipitated. After filtering and washing with ten per cent. boiling strontium solution, the strontium was removed with carbon dioxide. The sugar thus obtained, calculated

No. 1 is beet wash-water from the washing machine. Yellowish-brown, when examined in a layer two centimetres thick; opaque; contained earthy matter, fibres, etc. No. 2 is boneblack wash-water. Turbid, yellowish-grey, with numerous suspended particles. No. 3 is osmose-water. Clear yellow, with smell of syrup. No. 4 is the entire waste-water as it leaves the works, after passing two large settling-tanks. Turbid, with a very

from its rotary power, gave an apparent value of 103.3 per cent.

This double precipitation was twice repeated, the numbers rising to 108.4 and 109.2. Complete separation was now effected by fractional precipitation with alcohol. To the syrup, now rich in raffinose, absolute alcohol was added until a permanent turbidity was observed in the hot solution. After twelve hours a

syrupy layer very rich in raffinose had separated. This was treated twice in the same way. Lastly alcohol was added in the cold until the turbidity just disappeared on shaking, the flask was then closed and the solution allowed to stand. After some days the raffinose separated in tufts of needles, which were completely purified by recrystallisation from alcohol. A description of the sugar will be given in a future paper.—S. Y.

*New Sweet Compound and Process of Manufacturing the same.* J. Y. Johnson, Middlesex. From Constantin Fahlberg, New York, U.S.A.; and Adolph List, Leipzig. Eng. Pat. 6626, June 1, 1885.

By means of this invention a new sweet compound may be prepared from coal-tar or analogous substances, containing a considerable proportion of benzene, toluene, etc. The inventors name the new substance "Saccharine," although it is not related to the class of sugars, but is a derivative of benzoic acid. The scientific name of the substance is benzoysulphimide, and it has its composition represented by the formula— $C_7H_5.CO.NH.SO_2$ . It possesses a taste similar to saccharose, but far sweeter, so that it may be employed as an advantageous substitute for sugar in all cases where the latter would be too expensive; for instance, in sweetening glucose, grape or starch sugar, and in other cases where cane-sugar is used for sweetening and preserving. A very diluted solution thereof tastes like a saturated solution of cane-sugar, and it has high antiseptic properties, which will further recommend it for many purposes in the arts and medicine. Owing to the fact that "saccharine" cannot be classed under the heading of nourishments, like sugar and similar carbohydrates, it may be used for many medical purposes where cane-sugar is excluded from the diet of certain patients, as in cases of "diabetes mellitus," and other diseases. Saccharine is difficultly-soluble in cold water; it is more soluble in warm or hot water, and can easily be obtained from such solutions in crystalline form. Alcohol and ether dissolve it readily. It crystallises in thick short prisms, in all probability belonging to the monoclinic system; they are, however, small, and imperfectly formed. It fuses about 200° C., under partial decomposition. It forms salts with the alkalis and alkaline earths, etc., similar to those formed by cane-sugar, these salts having the same pleasant and sweet taste as pure saccharine. Two very complex methods of preparation are given, the nature of which may be indicated as follows:—Toluene is heated with sulphuric acid to form sulpho-acids, which are first converted into lime-salts, then into soda-salts, the latter being treated, after drying, with phosphorus pentachloride to form sulpho-chlorides, one of which is then treated with dry ammonia gas to form an amide, which after oxidation by means of potassium permanganate yields the potash salt of "saccharine" from which by precipitation with a dilute mineral acid the pure "saccharine" is obtained.—A. W.

## XVII.—(A) CHEMISTRY OF FOOD. (B) SANITARY CHEMISTRY. (C) DISINFECTANTS, Etc. (B) SANITARY CHEMISTRY.

*Notes on Lead Service-tubes for Water-supply.* S. Steiner. Chem. Centr. 16, 524.

The water-supply of Budapest is carried into the houses in leaden pipes. The pipe for the water of the Hygiene Institute, which served for these experiments, was 39m. long, and had been laid for ten years. A sample of water taken, after a quick stream had been allowed to flow through the pipe, contained 0.085mllgrm. lead per litre; after a slow stream, 1.04mllgrm.; the water in the pipe after standing for twenty-four hours contained 1.224mllgrm.; after forty-eight hours, 1.7mllgrm.; after seven days, 3.25mllgrm.; and after a month, 4.7mllgrm. The water taken from the street-hydrant contained no lead. The amount of lead present was determined by evaporating the water with nitric acid, then treating with hot hydrochloric acid, and precipitating with sulphuretted hydrogen; finally weighing as lead sulphate.

—S. R.

*Clarification of Waste Waters from Dyeworks.* E. Hankel. Mittheilungen des Gewerbe-Museums in Wien, May, 1885.

To effectually clarify the waste-water from dyeworks it is recommended to treat the water with lime, allow the mixture to settle, draw off the supernatant solution, and pass the sludge through filter-presses.—D. B.

*Purification of Water according to the Gaillot and Huot System.* Mittheilungen des Techn. Gewerbe-Museums in Wien, May, 1885.

THIS process involves the use of caustic lime and caustic soda. The purified water contains sodium sulphate and sodium chloride—i.e., salts which are perfectly harmless. The practical results achieved are very satisfactory, as will be seen from the following figures showing the hardness of the water before and after purification:—

	Hardness before purification.	Hardness after purification.
1.	23—27	2—4
2.	29	2—5
3.	39—42	3—5
4.	42	4—6
5.	26	4—5
6.	38—40	3—5

—D. B.

*Poisoning by Coal-Gas and Charcoal Fumes.* J. Poleck. Rep. Anal. Chem. 5, 225.

THE author published together with Biefel, in the *Zeit. Biol. Chem.* 1880, an investigation of this subject, which has been subjected to a lively criticism by A. Wagner (*Rep. Nov.* 1884). Against the strictures of the latter the author enters a strong protest, especially vindicating the methods adopted for collecting the gases, and the results of their analysis.—C. F. C.

## XVIII.—ELECTRO-CHEMISTRY.

*Improvements in the Manufacture of Phosphates.* Ph. M. Justice, London. From Sidney Gilchrist Thomas, Paris. Eng. Pat. 11,805, August 30, 1884.

THIS invention relates to the manufacture of phosphates free from iron, from phosphoric slags and minerals containing iron. The material is dissolved in acid, and the current from a dynamo-electric machine passed into the nearly neutral solution until the whole of the iron is deposited. The free phosphoric acid may be used for preparing high-class phosphates.—S. Y.

*Improvements in Secondary Batteries.* Ernest George Dornbusch, London. Eng. Pat. 11,553, Sept. 1, 1884.

IN Faure's and other secondary batteries in which the electrodes are enclosed in, or separated by means of felt, flannel, or other suitable absorbent material, the salt of lead is liable to penetrate through the material and establish short circuits between the two electrodes forming the secondary couple. The inventor taking account of this penetration of the lead salt through the absorbent material, makes the latter a carrier or support for the active substances. The lead plates are slit into strips from a short distance from one edge right down to the opposite edge, and the felt or other material is folded backwards and forwards so as to completely cover the plates. The prepared plates are then impregnated with the lead compound, and finally dipped into a paste of red lead and water. They are then placed in bags of felt or flannel, and reduced or peroxidised to form the elements of the secondary battery.—S. Y.

*Carbon Fabrics or Materials, their Manufacture and Application.* Joseph Stokes Williams. Eng. Pat. 12,065, September 5, 1884.

THIS method of manufacturing carbon sheets, ribbons, fabrics, plates, or rods for use in electrical work consists

in impregnating vegetable matter, moulded or woven into the desired shape, with starch, dextrin, or finely-divided wood pulp or paper, and subsequently carbonising in a chamber charged with hydrocarbon vapour. The material may also be impregnated with finely-divided carbon, and the subsequent carbonising be performed by passing a strong current of electricity through it.—E. J. B.

*Improvements in Apparatus for Lighting Gas and other Inflammable Substances.* James Grieve Lorrain, London. Eng. Pat. 12,139, September 8, 1884.

THE apparatus is a form of continuous electrophorus or convection induction machine, by means of which sparks are made to pass between two outer points. Various devices for causing rotation are described, and methods are adopted for regulating the distance between the points, and for securing perfect insulation and dryness.—S. Y.

*Improvements in Secondary Batteries or Accumulators.* Desmond Gerald Fitz-Gerald, Brixton. Eng. Pat. 12,350, September 12, 1884.

THE object of this invention is to diminish the time required to "form" the plates in the secondary battery of the Plante type, and to allow of the substitution in other forms of accumulator of a simple plate of lead in place of anodes of more complicated structure. The invention consists in employing a solution of magnesium sulphate as the electrolyte in charging the secondary battery. As the solution becomes acid, magnesia or magnesium carbonate is added. When the battery is discharged the magnesium sulphate may be replaced by dilute sulphuric acid. The process of "forming" can thus be effected by one reversal of the current, that is, by two operations of charging in opposed directions. The solution of magnesium sulphate is also applied to those batteries in which the lead plates are roughened, corrugated, or perforated, in which case only one operation of charging is required.—S. Y.

*Improvements in Voltaic Batteries.* Desmond Gerald Fitz-Gerald and T. J. Jones, London. Eng. Pat. 12,802, September 25, 1884.

THE inventors point out that zinc is unsuitable for the positive element of a primary battery, because it is impossible economically to recover the zinc in the metallic state from the sulphate. They propose to employ spongy lead as positive elements, and lead peroxide as negative elements, and the essential feature of the invention consists in the conversion of sulphate of lead into spongy lead to form the positive elements, and of spongy lead prepared in this or other ways into lead peroxide for the production of negative elements, both operations being performed by means of electrolysis. In the first operation a pasty mass of sulphate of lead and magnesia or an alkali, is spread on lead plates, and after hardening the sulphate is reduced in tanks in which the electrolyte is magnesium sulphate. In preparing the negative element the spongy lead is allowed to oxidise partially in the air, and is peroxidised by means of electrolysis.—S. Y.

*Improvements in Primary or Galvanic Electric Batteries and in their Construction.* Blanche A. Rowan, Southsea. Eng. Pat. 13,744, October 17, 1884.

By using broken carbon, moistened with a solution of any metallic nitrate, such as the nitrate of mercury, silver, aluminium, chromium, lead, copper, or iron, enclosed in an envelope or hollow cell of carbon to form a negative electrode, and as a positive electrode zinc immersed in a solution of any suitable chloride, such as sal-ammoniac, a battery is formed having a constant current and a high electromotive force.—T.

*A Compound Galvanic Battery.* S. H. Emmiens, London. Eng. Pat. 13,759, October 17, 1884.

THE compound battery referred to, consists of a primary charging a secondary battery, the cells of each class being of any known construction. This combination reduces the labour of charging and discharging, the electromotive force of the primary battery being easily brought to any required degree of tension. Constant action of the secondary battery is maintained by replenishing the primary battery while at work.—T.

*Improvements in the Preparation or Manufacture of Elements for Primary Electric Batteries.* C. P. Elieson, Essex. Eng. Pat. 14,197, October 27, 1884.

PLATES or other pieces of carbon are placed in water or other solution capable of giving off oxygen, a current of electricity is then passed through the carbon in order to charge it with oxygen. After having been charged to the desired extent, the plates or pieces are removed from the liquid and exposed to the air, in order that they may become thoroughly oxidised. By using carbon prepared in this manner, the efficiency of a battery is greatly increased on account of no rapid polarisation taking place.—T.

*Improvements in Galvanic Batteries.* Gustavus Baron de Overbeck, London. Eng. Pat. 14,485, November 1, 1884.

IN order to prevent the polarisation produced in batteries by the formation of bubbles of hydrogen on a carbon or other insoluble electrode, the author proposes to use an aqueous solution of a hypochlorite salt, or free chloric acid, or free perchloric acid, adding as may be suitable sodium or potassium chloride.—T.

*Improvements in and connected with Electric Batteries or Elements.* P. M. Justice, London. Eng. Pat. 14,548, November 4, 1884.

THIS invention has for its object the more complete separation of the liquids in hydro-electric elements or batteries of two liquids by means of a porous membrane of gold-beaters' skin, amiantus or ordinary paper, or by a porous ring or disc of terra-cotta, or the like placed in a slanting position between the heavy and lighter liquid, and having a tube inserted into it in such a way that the gases formed can escape through the tube without disturbing the liquid above.—T.

## XIX.—PAPER, PASTEBOARD, Etc.

*Improvements in Treatment of Xylonite, etc.* A. J. Boulton, London. From W. C. Zeidler, Toronto. Eng. Pat. 8012, July 1, 1885.

THE object of this invention is to provide a simple, quick, and effective process for polishing the surface of celluloid, xylonite, zylonite, chrolithion, pyroxyline, and similar substances, and at the same time to secure the said material when made in any shape to wood or other material. It consists essentially in submitting the celluloid or like material to pressure while treated, and preferably cooling the same off. Only a few minutes are occupied in pressing, heating, and cooling. "By the adoption of this process it only occupies about five minutes from the time that the celluloid is first glued on to the board until it is polished and finished ready to be cut into keys, etc."—H. A. R.

*Improvements in the Manufacture of Vegetable or Paper Parchment.* T. R. Shillito, London. From C. Arnold, Germany. Eng. Pat. 8130, July 4, 1885.

THE main points of interest in this invention are the following:—1. In the manufacture of the parchment the method of washing out the acid from the material under treatment by the repeated use of the same acidulated

water until its degree of concentration has reached a certain point, for the purpose of the more advantageous recovery of the acid substantially as described and illustrated. 2. A chest, which is cooled by fresh water, and from which the acidulated water is continuously removed where it is least saturated with acid, and is conducted to the jet-pipes for this purpose, as described in the specification. The drawing should be consulted.

—H. A. R.

*Improved Process of Preparing Sulphate of Lime for Paper-making, etc.* C. W. Knowles, Nova Scotia. Eng. Pat. 12,193, September 9, 1885.

INVENTOR prepares a thick or semi-solid pulp of the sulphate with water, in a convenient form for immediate use, or for transit, packing, etc.—H. A. R.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*Liquid Carbonic Acid.* H. Herberts. Chem. Centr. 16, 558, 560, 572.

LIQUID carbonic acid can now be bought in iron or steel bottles containing Skilos. of the liquid, which corresponds to about 4000 litres of the gas at ordinary temperature and pressure, and costs about 1 mark per kilo. At this price it furnishes the cheapest means for aerating beer and mineral waters, and is also extensively used for raising sunken ships, for driving torpedoes, for extinguishing fires, for cooling purposes, and by the firm of Fr. Krupp in Essen for the condensation of steel and other metals, and is further suggested as a motive power for trams and air balloons. In the German patent No. 28,769, a method for the preparation of carbonic acid and Glauber's salts from acid sulphates (disulphates) is described. A bisulphate containing 70 per cent. of sodium sulphate, and 25 to 30 per cent. of free sulphuric acid can be used with advantage. The apparatus employed is described in detail in the specification, and consists essentially of a leaden vessel containing a solution of the bisulphate, and having a stirring apparatus and gear fixed airtight to it. By means of a tube and pump an equivalent quantity of chalk or other carbonate suspended in water in a second vessel can be forced into the first, and the stirrer is then set in motion. The liberated carbonic acid passes through a suitable drying apparatus to a gasometer, from which it is afterwards condensed. The residue consisting of calcium and sodium sulphates is removed to a filter press, and the sodium sulphate crystallised or calcined from the filtrate. The calcium carbonate employed is that obtained as a waste product in the manufacture of caustic. It is suggested that magnesium carbonate should be substituted for chalk, thereby getting no precipitate but a double sulphate of magnesium and sodium which could be used for the preparation of sulphuric anhydride. By the evaporation and expansion of the liquid carbonic acid, a large quantity of heat is absorbed. An apparatus is described for allowing this to take place round a tube containing a solution of calcium chloride; the latter is so cooled that it can be used for freezing water and the manufacture of ice. The carbonic acid, which is thus used, passes over sodium carbonate, which is thereby converted into bicarbonate if care be taken that the necessary amount of moisture is present. The bicarbonate formed in this way is used over again in the carbonic acid manufactory.—S. R.

*On Artemisia Gallica, Wild., as a Source of Santonin, and on its Chemical Composition.* Ed. Heckel and Fr. Schlagdenhauffen. Compt. Rend. 100, 804—806.

THIS plant, which is widely distributed in France, contains 1 per cent. of etheral oil, and a crystalline body (camphor?) volatile with steam. The flowers give 3 per cent. of extract with petroleum, consisting chiefly of wax, a yellow colouring matter and some chlorophyll. The chloroform extract contains considerable quantities of santonin, and a resinous body apparently isomeric

with santonin. The alcoholic extract from the whole plant contains glucose, tannin, colouring matter, and an alkaloid.—S. Y.

*Paraldehyde as a Remedy against the Poisonous Action of Strychnia.* Árpád Bokai. Chem. Zeit. 9, 960.

THE author has found in paraldehyde a powerful antidote against poisoning by strychnia. Hitherto chloralhydrate has been used, but owing to its powerful action on the heart, paraldehyde is recommended. It is said to act as counter poison to brucine, thebaine and picrotoine.—D. B.

*The Estimation of Glycerol in Aqueous Solution and in Fats.* R. Benedikt and R. Zsigmondy. Chem. Zeit. 9, 975.

THE authors find that the method adopted by Fox for the detection of glycerol in linseed-oil varnish is, if conducted with certain precautions, capable of giving accurate quantitative results when applied either to the estimation of glycerol in aqueous solutions or to the oxidation of fats. The method depends upon the oxidation of glycerol, by permanganate in alkaline solution, to oxalic acid, carbon dioxide, and water, in accordance with the equation—

The following are the details to be observed in the estimation of glycerol in aqueous solutions: An amount of solution which shall contain about 0.2–0.5 gm. of glycerol, is rendered alkaline by the addition of 10 grm. of pure potassium hydrate, and then potassium permanganate, either as a five per cent. solution, which is best, or in the solid form, added until the liquid appears almost black. The mixture is heated to boiling, whereby a separation of manganese dioxide takes place, decolourised by means of sulphurous acid, passed through a filter of sufficient size to hold at least one-half of the liquid at once, and the residue well washed with boiling water. The filtrate is acidified with acetic acid, which, by setting free sulphurous acid, causes the removal of any turbidity due to manganese peroxide. The filtrate is then precipitated with acetate of lime. The precipitate contains sulphate of lime and silicic acid in addition to calcium oxalate, hence the amount of oxalic acid cannot be inferred from the weight of the residue after ignition, but is to be arrived at either by titration of the precipitate with permanganate in acid solution or by determining the alkalinity of the ignited precipitate. Test analyses gave 90.3, 91.4, 92.3, and 92.7 per cent. of glycerol instead of 91.0 per cent., and in a dilute aqueous solution containing 0.05 per cent., this method gave 0.0507 per cent., 600 grm. being taken for the analysis. For the determination of glycerol in fats, from two to three grammes of ordinary fats, and from ten to twenty grammes when the proportion of glycerol is small, will be found sufficient. The fat is saponified with potassium hydrate and pure methyl alcohol, the alcohol evaporated off, and the soap dissolved in hot water, and decomposed by dilute hydrochloric acid in excess. Heat is now applied to effect the complete separation of the fatty acids, and, in the case of liquid fats, some hard paraffin is added to assist the solidification of the fatty acids, the dish being set in cold water. The acid liquid is filtered into a capacious flask, the fatty acids being well washed with water; the filtrate is neutralised with potash, and, after a further addition of 10 grm. of potassium hydrate, the glycerol estimation proceeded with, as described above. The authors employ methylic and not ethylic alcohol in the saponification, since the latter is completely expelled from the soap with difficulty, and under certain conditions of alkalinity and concentration of the solution, is oxidised by permanganate to oxalic acid. It has been found by experiment that the soluble fatty acids—viz., acetic, butyric, and caproic—do not, when subjected to the oxidation process above described, yield any acids precipitated by lime in acetic acid solution. The authors have obtained the following results with various fats:—Olive-oil, 10.15–10.38 per cent. of glycerol; linseed-oil,

9.45–9.97; cocoa-nut oil, 13.3–14.5; tallow, 9.94–9.98; butter, 10.21–11.59; Japan-wax, 10.3–11.2; bees-wax, 0.00. Since the fats contain, upon an average, 10 per cent. of glycerol, which is not found at all in beeswax, the percentage of fat in a sophisticated beeswax may be calculated with sufficient accuracy for technical purposes, by multiplying the percentage of glycerol found by ten.—W. D. B.

*Examination of Essential Oils.* H. Hager. Pharm. Centr. 1885, 316.

FOR the examination of certain essential oils, chiefly with the view to distinguish the "natural" products from artificial imitations, the author employs an aqueous solution of mercuric nitrate (10 per cent.). Four drops of the essential oil are dissolved in 2 cc. of alcohol, and 2 to 3 drops of the nitrate solution added. No reduction occurs with the essential oils of laurel (ol. lauro cerasi) and bitter almonds. The greater number of oils, however, have a reducing action on the nitrate, and their presence in admixture with the above is indicated by the formation of a grey precipitate of metallic mercury. The artificial bitter almond water also precipitates the solution, and is thus distinguished from the natural. The following oils—viz., ol. cassie cinnamon, succini, petric, linanthracis, vince, vitis viniferae—do not readily reduce the nitrate, but their presence in bitter almond oil is indicated by the opalescence occasioned by diluting with alcohol (6 parts of sp. gr. 0.895). Mustard oil treated under the above conditions gives a slight reduction; the artificial products sold under this name were found, on the other hand, to reduce rapidly, giving a dark-grey precipitate.—C. F. C.

*Papaverin.* G. Goldschmidt. Monatsh. Chem. 6, 372.

IN continuation of a previous communication (*Ibid.* 4, 704) the author gives the results of a further investigation of the oxidation of papaverin by potassium permanganate in dilute aqueous solution at the boiling temperature. In addition to carbonic and oxalic acids and ammonia, the following products of the reaction were isolated:—(a) Dimethylprotocatechuic acid (melting point 180°); (b) an acid body which, from its composition,  $C_{16}H_{11}O_9$ , melting point 180°, and reactions, appeared to be hemipic acid (*Ibid.* 3, 351); (c) the main product, which is an acid, having the composition  $C_{16}H_{13}NO_7$ , melting at 233°, and termed by the author papaveric acid. It is a dibasic acid, giving both acid and basic salts with the alkali metals. The following salts are described:—

The acid forms a compound with hydrochloric acid, and is obtained from its solution in the latter in slender yellow needles,  $C_{16}H_{12}NO_7 \cdot HCl \cdot 2\frac{1}{2}H_2O$ . The acid is easily converted into the mononitro derivative,  $C_{16}H_{12}(NO_2)NO_7$  (melting point 215°) by treatment with nitric acid, dilute as well as concentrated, and by nitrous acid in acetic acid solution. Papaveric acid heated in a stream of hydrogen at a temperature (235°) a little above its melting point, loses  $1mol. CO_2$ , and is converted into pyropapaveric acid,  $C_{16}H_{13}NO_7$ . The chief product of the fusion of the acid with potassium hydrate is protocatechuic acid. Lastly, the author isolated from the products of the oxidation of the papaverin by permanganate an acid (d)  $C_{16}H_9NO_8$ , melting at 249°, and identified as  $\alpha$ -pyridinetricarboxylic acid. The following statistics are given of the yield of these several products: From 264.5 grm. papaverin an aggregate of 100.3 grm. of crystalline products was obtained, from which were isolated—

	Grm.
(a) Dimethylprotocatechuic acid.....	9.9
(b) Hemipic acid.....	6.8
(c) Papaveric acid.....	40.2
(d) $\alpha$ -Pyridinetricarboxylic acid.....	12.0
Oxalic acid.....	12.4

In conclusion, the author applies these results to the discussion of the constitution of papaveric acid, regarded as the immediate product of the oxidation of papaverin, and as yielding by further resolution the products *a*, *b*, *d*. The experimental evidence is summed up by the constitutional formula—

which the author adopts as the working hypothesis for further investigations.—C. F. C.

*Adulteration of Tartar.* Zincker. Rep. Anal. Chem. 5, 245.

TARTARS, which are sold in powder, are sometimes adulterated with alum, usually to the extent of about 20 per cent. In four samples, examined by the author, the quantities estimated were 20.6, 26.7, 5.4 and 22.9 respectively. Indications of this adulteration are afforded by the percentage of water which in the normal product does not exceed 2 per cent., whereas in the adulterated article it may amount to 8–10 per cent. If this indication is confirmed by the sulphuric acid reaction, the alumina should be determined, after igniting the specimen.—C. F. C.

*Identification of Alkanet.* H. W. Vogel. Rep. Anal. Chem. 5, 245.

THE author points out, in reference to a recent communication of J. Herz (*Ibid.* 210), that the colouring matter of the alkanet is most easily identified by the characteristic absorption spectra of its solutions. The solution in amyl alcohol gives the best results. On adding ammonia, the three bands, in the blue green, give place to two, situated one on either side of the D line.—C. F. C.

*Improvements in the Manufacture of Chloroform and Acetic Acid or Purified Acetates.* From Gustavus Michaclis and William Turner Mayer, New York, U.S.A. Eng. Pat. 8523, July 1, 1885.

THIS invention claims the process of producing chloroform and valuable residual products, by subjecting crude acetates to dry distillation at high temperatures, removing the fluid products, and subjecting them to the action of hypochlorites, condensing the chloroform therefrom and subsequent purification. Also the production of acetic acid or acetates from the residuals. The invention is based on the discovery that when a crude acetate, as of lime, is subjected to dry distillation, only very small quantities of acetone ( $CH_3CO.CH_3$ ), boiling at 56°, are formed, whilst very considerable quantities of dimethyl-acetal  $C_2H_5(OCH_3)_2$ , boiling between 60° and 65°; ethylmethylacetal  $C_2H_5(OC_2H_5)OCH_3$ , boiling at about 85°; methyl ethylketone ( $CH_3CO.C_2H_5$ ), boiling between 75° and 80°; diethylketone ( $C_2H_5CO.C_2H_5$ ), boiling between 75° and 85°; metacetone  $C_6H_{10}O$ , boiling between 82° and 86°, and other still higher boiling ketones, as dumasins and other liquids, together with a large quantity of an apparently oily substance, which also holds some of the before-stated ketones in solution, are the result of the process. The further discovery that while pure acetone yields when distilled with a hypochlorite 33 per cent. of chloroform, the above enumerated ketones and other liquids, all of which possess higher boiling points than does acetone, will yield, when freed from water and treated with a hypochlorite, chloroform in the large and unprecedented quantity of measure for measure.—T.

## XXII.—GENERAL ANALYTICAL CHEMISTRY.

*Detection and Estimation of Iodine.* E. H. Cook. J. Chem. Soc. (Trans.), 1885, 471.

ON adding hydrogen peroxide to a solution acidified with acetic acid, and containing chlorides, bromides and

iodides, only the iodine is liberated in the free state, and the separation gives very good results when used for quantitative determinations, as the results show.

—G. H. B.

*Colorimetric Method for Determining Small Quantities of Iron.* A. Thompson. J. Chem. Soc. (Trans.), 1885, 493.

THIS method is an application of the reaction between ferric salts and thiocyanic acid, and is available in presence of large quantities of most other metals to estimate minute quantities of iron. Mercuric chloride must be absent. The substance to be examined is dissolved in a suitable acid, and the solution evaporated to expel excess of acid. After oxidation of ferrous to ferric iron by the addition of a permanganate solution, potassium thiocyanate is added, and the colour produced is compared with that obtained with known quantities of iron. Figures are given to show the degree of accuracy obtainable.—G. H. B.

*An Apparatus for Fractional Distillation under Reduced Pressures.* A. Gorboff and A. Kessler. Ber. 18, 1363.

THE authors describe a modification of Kononov's apparatus (Ber. 17, 1535), which may be employed for large quantities of substance. In the diagram *a* is an ordinary cork, well paraffined and encircled by an indiarubber ring *f*, to make it quite air-tight. The indiarubber cork *e*, through which the glass rod *d* passes, fits into

a glass tube *b*, which passes through *a*. The end of the distillation apparatus is represented by *g*, and connection with the pump is effected by the tube *i*. If the glass rod is well greased, it may be readily turned, even at so low a pressure as 16mm., so as to bring each receiver in turn under the tube *g*.—S. Y.

*Apparatus and Arrangements of the Dresden Laboratory.* Walther Hempel. Ber. 18, 1434.

(1.) *Laboratory Filter-Press.*—The filter proper consists of two perforated porcelain plates, between which is a thick indiarubber ring, perforated with one hole to admit a glass tube, which conveys the precipitate and wash water into the filter. The glass tube is connected with an upright glass tube, two or three metres long, and provided at the top with a funnel into which the precipitate and liquid, and afterwards the wash-water, are poured. The filter rests on two slabs of glass, supported by an iron frame, the lower edges of which rest on a split glass tube, forming a trough through which the filtrate runs, and falls into a beaker placed below and at one end of the slightly sloping trough. When the apparatus is to be used the porcelain discs are separated, on one of them is placed in succession a piece of coarse linen suitably cut, a filter paper, the indiarubber ring, a second filter paper, another piece of linen, and finally the second porcelain disc. The filter is pressed together by iron screws covered with indiarubber, and the discs are protected from the screws by pieces of wood or hard rubber. The glass tube at first passes well into the filter, but after the precipitate has formed a moderately coherent cake,

it is withdrawn as far as the indiarubber ring, leaving a canal. The wash-water fills this canal and penetrates the whole of the precipitate. The indiarubber rings should be kept under water when not in use.

(2.) *Draught for Poisonous Gases.*—In place of the ordinary large and somewhat dark draught chambers, the author makes a long narrow orifice in the wall of the chimney, and places above this a sloping glass plate, supported by T-shaped iron pieces. The evaporating basin or other vessel is placed below the glass roof, and the vapours are carried away by the current of air.

(3.) *Apparatus for Preparing Hydrofluoric and Hydrofluosilicic Acids.*—The author employs cast-iron vessels in preference to lead or platinum. The apparatus consists of a flanged pot and cover, which are held together by four screw-clamps. In the centre of the cover is fitted an iron gas-pipe, 30mm. wide, at the upper end of which is a three-way piece, open at the top, and leading at the side to a lead tube, to which it is connected by a flange. The tube may be closed at the top by a cork. The lead tube passes to the absorption apparatus, which is a lead cylinder 15cm. wide and 70cm. high, closed at the top by a perforated lead basin, and fitted at the bottom with a leaden exit tube. A narrow lead tube passes down one side of the cylinder, forms a coil at the bottom and passes up the other side. By allowing a current of water to circulate through this the apparatus is kept cool. The cylinder above the coil is filled with pieces of charcoal. The mixture of fluor spar and concentrated sulphuric acid is heated in the iron pot by a naked flame, and the gas passes into the cylinder, in which it is absorbed by water which is placed in the perforated basin at the top, and moistens the charcoal. Pure ammonium fluoride is prepared by dividing the crude acid into two portions, neutralising one with ammonia, and then adding the other. The liquid is evaporated in a platinum basin, and allowed to crystallise. For hydrofluosilicic acid the lead delivery-tube is replaced by a glass one, which dips under water. If a tube 15mm. wide is employed, mercury may be dispensed with.

(4.) *Oxygen Apparatus.*—This was seen by the author in New York, but he could not discover the inventor. It resembles the apparatus for hydrofluosilicic acid, but the upper end of the three-way tube is connected with a large funnel fitted with a stopcock. 50grm. of potassium chlorate at a time are shaken through the funnel into the pot which is heated by a naked flame. The stopcock is closed when a glowing taper is rekindled in the funnel.

—S. Y.

*Vacuum Desiccator with Appliance for Heating.* R. Anschutz. Ann. 228, 305.

THE apparatus illustrated by the accompanying drawing, serves to heat a liquid contained in a vacuum desiccator

without affecting the vacuum. The heating arrangements consist of a thin lead pipe, both ends of which are

passed through a cork fitted into the neck of the bell jar. A glass tube communicating with the air pump and vacuum gauge also passes through the cork. The lead pipe is rolled together to form a spiral, both sides of which are covered with nickel wire gauze. This forms a portable bed for the substance to be dried. The heating agent is then allowed to circulate through the pipe.

—D. B.

*On the Volumetric Estimation of Nitrogen.* H. Hufschmidt. Ber. 18, 1441.

THE author finds that the results given by Dumas' method are always too high owing to the air given off on heating the sodium bicarbonate or manganese carbonate, and he recommends the use of marble and hydrochloric acid heated nearly to its boiling point, which gives better results even than sodium carbonate and sulphuric acid. With marble three litres of carbon dioxide were found on an average to contain 0.2cc. of gas unabsorbed by caustic potash. In an analysis the author passes about three litres of carbon dioxide to drive out the nitrogen, and subtracts 0.2cc. from the real volume of nitrogen. A modification of Zulkowsky's nitrometer is recommended.—S. Y.

*A New Method for the Volumetric Determination of Sulphur.* N. Klobukow. Ber. 18, 1861.

THE process has for its object the estimation of the total amount of sulphur in all compounds which can be decomposed by acids. It is based on the fact that hydrogen *in statu nascenti* converts under certain conditions sulphur and sulphur dioxide into sulphuretted hydrogen, which can be determined by titration with iodine. The method is carried out in the following manner:—The substance to be tested is put into a flask which is connected with a hydrogen apparatus and an absorbing arrangement. It is also fitted with a separating funnel which supplies the acid necessary for the decomposition. The absorbing arrangement consists of a spacious flask, through whose neck a glass tube reaches down to the bottom, and which holds standard iodine solution and two Liebig's potash bulbs, one containing iodine solution and the second potassium iodide solution. After bringing the weighed substance or measured solution into the decomposing flask, water and granulated zinc, free from sulphur and arsenic are added, and hydrogen passed through the apparatus for about 10 minutes. The acid is then allowed to flow gradually from the separating funnel into the decomposing flask. Either of two cases may now occur: either sulphur dioxide is given off along with the appearance of a precipitate of elementary sulphur, or no sulphur is precipitated. In the first case the flask is cooled by being placed in a dish with cold water, while the decomposition is carried on very slowly. The liquor which is at first turbid gradually becomes clear. The cooling is then discontinued, more acid is added, and the flask gently heated until all the zinc is dissolved. The heat is then raised to 70–80° C., the current of hydrogen increased to produce agitation until all traces of sulphuretted hydrogen are driven into the absorbing flask. If no elementary sulphur is separated in the decomposing flask, the cooling can be dispensed with. If the substance originally contained sulphuric acid or this acid was formed during the decomposition, it will be found in the decomposing flask, and can be estimated in the usual manner.—S. H.

*Remarks on the Analysis of Potassium Permanganate and Manganese Peroxide by means of Hydrogen Peroxide.* G. Lunge. Ber. 18, 1872.

In a former paper on "New Applications of the Nitrometer" (*Journ. Soc. Chem. Ind.* 4495) the author recommended the decomposition of permanganate of potash by means of hydrogen peroxide in excess, whereby the oxygen given off represents double the amount of active oxygen in the permanganate. Martinon (*Zell. Soc. Chim.* 1885, 355) states that a precipitate of manganese peroxide is formed on adding acid hydrogen peroxide to neutral permanganate or neutral hydrogen peroxide to

acid permanganate. Consequently according to the latter 6K<sub>2</sub>MnO<sub>4</sub> and 9H<sub>2</sub>O<sub>2</sub> give off 9O<sub>2</sub>, whereas according to Lunge, 6K<sub>2</sub>MnO<sub>4</sub> and 15H<sub>2</sub>O<sub>2</sub> act upon each other, generating 15O<sub>2</sub>. Lunge now shows that the precipitate of manganese peroxide can be avoided, if sufficient sulphuric acid is present and the hydrogen peroxide is in excess, and is added all at once. If these precautions are observed, the analysis of permanganate by hydrogen peroxide and by ferrous sulphate give identical results. A further argument that Martinon's reaction does not take place is furnished by the fact that manganese peroxide in acid solution reacts with hydrogen peroxide, thus: MnO<sub>2</sub> + H<sub>2</sub>O<sub>2</sub> = MnO + H<sub>2</sub>O + O<sub>2</sub>. On this reaction Lunge bases a manganese peroxide test by means of the nitrometer which is very accurate, can be done in very little time, and requires no balance, or weights, etc.

—S. H.

*Diphenylamine and Crystallised Phenol as Reagents for Nitrates and Nitrites.* H. Hager. Chem. Centr. 16, 556, 588.

DIPHENYLAMINE has been used as a test for nitrates and nitrites in concentrated sulphuric acid for several years. The author, however, has modified the method so as to render it sharper. He uses the diphenylamine in two forms—the one is a solution consisting of 1grm. diphenylamine dissolved in 30cc. absolute alcohol, the other is a mixture of this solution with five or six times its volume of pure concentrated sulphuric acid. Oxidising agents—*c.g.*, chromic acid, manganic oxide, ferric oxide, arsenic, iodic, chloric, tungstic, and molybdic acids, the salts of these substances and chlorine gas also produce a blue colouration, whilst manganous and ferrous salts, arsenious and oxalic acids if present may hinder the formation of the blue colour. The method of testing is as follows:—About 1cc. of pure concentrated sulphuric acid is poured into a reagent cylinder, and three to four drops of the diphenylamine solution added and well mixed. On to the surface of this is gently poured 3 or 4cc. of the solution to be tested; the blue colour will be produced at the junction of the two liquids if a nitrate or nitrite be present. If the liquid to be tested be first introduced into the cylinder, and the diphenylamine sulphate solution be poured gently down the side of the tube, it will sink to the bottom of the vessel, and will be completely coloured blue. This last method gives better results than the first. One drop of 30 per cent. nitric acid in 60cc. of water gives a distinct dark blue colouration. With smaller quantities of nitric acid, if no blue colouration is obtained, the two liquids are mixed by agitating the cylinder, and an additional quantity of sulphuric acid gently added, and the whole allowed to stand for 30 minutes. One drop of 30 per cent. acid in 200cc. of water can be detected in this way. If chlorine be present the author then uses phenol in the following way:—To a few cc. of the suspected liquid 2 to 3cc. of 25 per cent. hydrochloric acid are added, and then a few crystals of phenol, and the mixture heated to 80 or 90° C. After cooling (?) 1 to 2cc. of concentrated sulphuric acid are gently poured down the sides of the cylinder, when at the junction of the two liquids a bright red colour will be produced. This phenol reaction can be used in the presence of ferric salts, arsenic acid, etc.—S. R.

*Diphenylamine, a Valuable Reagent for Detecting Free Chlorine.* H. Hager. Chem. Centr. 16, 588.

DIPHENYLAMINE furnishes even a more delicate test for free chlorine than it does for nitric and nitrous acids. A solution of diphenylamine sulphate is prepared by taking 1 volume of a 3.3 per cent. diphenylamine solution in absolute alcohol, and mixing with it 5 volumes of pure concentrated sulphuric acid. Four to five cubic centimeters of the liquid to be tested for chlorine, are poured into a test glass or cylinder 1cm. wide, and then so much of the diphenylamine solution is added, that after being cautiously poured so as to glide down the inside of the cylinder, it collects in a layer at the bottom. According as there is more or less chlorine present, the upper part of the layer of diphenylamine sulphate solution becomes instantly, or in the course of

a minute, coloured blue. Even with very small traces of chlorine, not detected with iodised starch paper, the reaction is evident. For very small traces of chlorine it is rendered more delicate still if 3 or 4 cc. of the solution to be tested are poured into a test tube, and then some 1 to 1.5 cc. of the diphenylamine sulphate solution are so added that the liquids form two layers. If the tube be suddenly agitated to cause complete mixing, a strong blue colour is at once formed, which only momentarily appears, and then vanishes. During the agitation a piece of white paper is held obliquely to the cylinder, so that the momentary appearance of blueness may be readily perceived. Suppose even on agitation no reaction ensue, then about 1 cc. of pure concentrated sulphuric acid should be run down the side of the cylinder so that it collects on the bottom, and forms a layer. The slightest trace of chlorine will now manifest itself by the sulphuric acid becoming blue. Traces of free bromine are not detected by the diphenylamine test.—W. S.

*Influence of Boric Acid on some Colour Reagents.* A. Joly. *Chem. Zeit.* 9, 779.

BORIC acid does not effect a change in the colour of the dye helianthin, tropæolin OO, or orange No. 3 (Poirier). The author therefore recommends the use of a standard solution of borax for the titration of acids instead of normal alkali.—D. B.

## Monthly Patent List.

### ENGLISH APPLICATIONS.

1885.

#### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

- 10750 A. Langdon, London. Improvements in apparatus or means for utilising heated air as motive power. September 11  
10761 H. C. Patterson and R. Miller, Glasgow. Improvements applicable to steam-boiler and other furnaces. September 11  
10803 J. Murrie, Glasgow. Improvements in apparatus for indicating temperature or pressure. September 12  
10893 G. F. Redfern, London.—Communicated by L. Evesque and M. H. Fontès, France. An improved apparatus for automatically registering and recording high temperatures. September 14  
10907 J. Murrie, Glasgow. An improved apparatus for separating vapours from liquids. September 15  
10942 J. B. Elliott, London. Improvements in filter-presses and in apparatus connected therewith. September 15  
11030 A. Pope and R. Mogg Bryant, London. A new composition for preventing and removing incrustation in steam boilers. September 17  
11271 E. W. Killick, London. Improvements in kilns. September 22  
11467 J. Pickering, Walton, Liverpool. Iron-jacketed hot-air furnaces for heating drying chambers. September 26  
11842 J. Gray, Glasgow. Improvements in centrifugal machines for separating liquids of different specific gravity. October 3  
12189 A. Gapper Southby and F. Delacourt Bayly, London. Improvements in the mode of and apparatus for making ice and pumping highly rarefied condensable vapours. October 13  
12195 W. P. Thompson, Liverpool.—Communicated by A. Backus, jun., United States. Improvements in or pertaining to furnaces. Complete specification. October 13  
12340 J. Gwynne and D. Home Morton, London. Improvements in or pertaining to centrifugal pumping machinery. Complete specification. October 15

#### II.—FUEL, GAS, AND LIGHT.

- 10773 H. E. A. Wallis, London. Improved construction and arrangement of apparatus for conducting gas flame heat to hydrocarbon containing vessels for increasing the brilliancy or lighting power of coal gas. September 11  
10784 G. A. Seboth, London. Improvements in and connected with apparatus or appliances for mixing air with coal and other gas or vapour, and the utilisation thereof for lighting purposes. September 11  
10967 E. Coniston Mills, Altrincham. Improvements in apparatus for mechanically feeding fuel into furnaces. September 16  
11188 T. Lowe, Old Radford. Purifying waste gas-lime and restoring for use again, for purifying gas and other purposes, and for utilising the products. September 21

- 11190 G. Pettigrew, Darlington. Improved arrangement of hydraulic main ascension pipes, and anti-dip valve for the manufacture of gas. September 21  
11268 W. Barraclough, London. A new and improved method of producing from kerosene oil of any density flame (producing light and heat) to be emitted through a burner without the aid of a wick for use in lamps, stoves, and heating apparatus, and improved apparatus for the purpose of effecting the same. Complete specification. September 22  
11338 R. Barker and H. B. F. Barker, London. Improved apparatus and appliances for consuming oils for the generation of steam, boiling of liquids, and like purposes, specially applicable to burning crude or unrefined liquid hydrocarbons. September 23  
11339 R. Barker, London. Improvements in means for heating furnaces for smelting or roasting. September 23  
11106 J. F. Smith and G. Duxbury, Leicester. An improvement in apparatus for heating all classes of public and private buildings. September 25  
11520 R. Walker, Sunderland. Making and manufacturing compound fuel. September 28  
11616 F. Ducher and A. Serrallier, London, and T. Piéplu, Paris. Producing light and heat by means of an apparatus to which we give the name of hydrocarburator. September 30  
11664 J. Foord and W. W. Paddon, London. Improvements in obtaining light and heat by the combustion of hydrocarbons, and in apparatus to be employed for this purpose. September 30  
11718 H. Howell, Liverpool. Improvements in apparatus for manufacturing illuminating gas from volatile liquid hydrocarbons. October 1  
11911 P. C. Bann, London. Improvements in the preparation of oxides of iron, for use in gas purification, or for other purposes. October 7  
12124 W. Smith, London. A new fuel. October 12  
12129 G. E. Davis, London. Improvements in the manufacture of illuminating gas. October 12  
12187 S. C. Joyce, W. Smith, and W. Neall, London. Patent non-charring wicks. October 13

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

- 12059 M. Beaumont Parrington, London. Improvements in coke-ovens and in doors for the same, and for other furnaces. October 10  
12295 H. Stier, Zwickau, Saxony. An improved process of extracting from carboniferous materials the products met with, the processes of converting into gases and of withdrawing gases (for instance, process of distilling, of smouldering, and the like). Complete specification. October 15

#### IV.—COLOURING MATTERS AND DYES.

- 10831 H. H. Lake, London.—Communicated by Wyth & Co., for Leonardt & Co., Germany. Improvements in the manufacture of colouring matters. September 12  
10937 H. J. Haddan, London.—Communicated by F. Bayer and Co., Germany. Improvements in the process of manufacturing paranitro-benzaldehydes. September 15

#### V.—TEXTILES: COTTON, WOOL, SILK, ETC.

- 10756 J. Smith, Jersey. Improvements in machinery for decorticating fibrous substances. September 11  
11053 O. W. G. Briggell, London.—Communicated by H. Pissier, Holland. Improvements in treating reea or ramch. September 17  
11120 J. Kenyon, London. A stiffening finish for crapes of all kinds, as silk, or silk and cotton, or cotton crape, also for linen, lace, or calico. September 25  
11361 G. Kassner, London. A process or manner of manufacturing caoutchouc, wax, fat, colouring matter, vegetable fibre, fibre wool, and cattle food from lactucarius plants, or from plants or vegetables bearing milky juice, or from their extracts, such as opium, lactuca, and their likes. September 29  
11660 G. F. Redfern, London.—Communicated by E. Frémy and V. Urbain, France. Improvements in obtaining and treating fibres from the barks of plants of the Urtica family, and the like. Complete specification. September 30  
11892 H. J. Haddan, London.—Communicated by J. Breuer, France. Machinery for decorticating ramie and other textile plants. October 6  
12044 G. F. Redfern, London.—Communicated by C. de Baillencourt, France. Improvements in or applicable to machinery or apparatus for treating flax, hemp, and other textile materials. Complete specification. October 9  
12055 W. H. Greenwood, Bradford. Improvements in apparatus for washing wool and other fibres. October 10

#### VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

- 12002 J. Robertshaw, Manchester. Improvements in machinery employed in dyeing, sizing, and wringing banks. October 9  
12150 S. Smithson, Bradford. An improved method of and apparatus for dyeing. October 13

## VII.—ACIDS, ALKALIS, AND SALTS.

- 10804 J. Ballantyne Hannay, Glasgow. Improvements in obtaining ammonia or its hydrochloride, and in apparatus therefor. September 12.
- 10842 G. F. Redfern, London.—Communicated by J. Walckenaere, Belgium. Improvements in treating acid vapours from chemical works. September 12.
- 10849 J. Kay, Hill, Burf. Improvements in the recovery of alkali and utilisation of by-products. September 14.
- 11151 J. Milligan, London. Improvements in the manufacture of calcined magnesia. September 19.
- 11178 P. A. Mawdsley and T. Macfarlane, London. Improvements in the manufacture of sulphur from alkali waste by means of metallic chlorides. September 19.
- 11219 F. G. Riley, London. Improvements in and relating to apparatus for generating carbonic acid gas. September 21.
- 11402 J. Brock and E. Saye, London. Improved means or apparatus for distributing or conveying acids or other liquids to the bottoms or tanks of chemical towers or to vats or other receptacles. September 26.
- 11542 T. H. Cobley, Dunstable. Improvements in the manufacture of vitriolous ash, and application of same to useful purposes. September 28.
- 11747 R. Fullarton, Glasgow. Improvements in the utilisation of alkali waste. October 2.
- 12132 S. Bowen Bowen, London. Improvements in apparatus for the concentration of sulphuric acid. October 12.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

- 11081 H. Venables, London. A new or improved method of glazing china, porcelain, earthenware, and tarian. September 18.
- 11208 A. Landier and C. Houdaille, London. An improved mode of decorating objects of glass, crystal, or ceramic ware. September 21.
- 11351 J. Slater, London. Improvements in ornamenting glass, china, or other vitreous surfaces. September 23.
- 11395 A. Dixon Brogan, Glasgow. Improvements in the manufacture of plate glass, and in apparatus therefor. September 24.
- 11431 A. Shaw, Hanley. An improved process to be employed in printing with metallic substances, such as gold, silver, and similar substances, in a liquid state, for ornamenting or decorating glass, porcelain, china, and fictile substances generally. September 25.
- 11589 A. M. Clark, London.—Communicated by La Société Appert Freres, and La Société Geneste-Herscher et Cie, France. Perforated glass, and processes and apparatus for manufacturing the same. September 29.
- 11681 W. Jones, London. Improvements in means for drying bricks and other articles of clay, porcelain, terra cotta, or earthenware, such improvements being applicable for drying purposes generally. October 1.
- 11728 H. Fitzroy Webb, Birmingham. Improvements in the manufacture of decorated glass ware. October 2.
- 11881 E. Powell, F. Bishop, W. W. Bishop, and J. Stonier, London. An improved manufacture of ivory porcelain. October 8.
- 11965 E. Powell, F. Bishop, J. W. Bishop, and J. Stonier, London. Improvements in the manufacture of ornamental porcelain and pottery. October 8.
- 12128 E. Lee, Leeds. An improved method of ornamentation of glass and other substances. October 12.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

- 10761 C. Smith, London. Improvements in facing tiles or plates for concrete constructions. September 11.
- 10841 J. T. Welch, London. Improvements in the manufacture of bricks, pipes, tiles, household utensils, and other kinds of pottery goods. September 11.
- 11034 R. Stone, London. Improvements in the manufacture of cement, and in machinery or apparatus in connection therewith. September 18.
- 11101 W. Hassall, London. An improved composition or cement specially applicable for use in jointing stoneware, concrete, or like pipes. September 16.
- 11098 E. Stone, London. Improvements in the manufacture of cement. September 18.
- 11174 J. Watson, London. Improvements in the manufacture of cement. September 19.
- 11270 E. W. Killick, London. Improvements in the manufacture of cement. September 22.
- 11282 J. Howie, Glasgow. An improvement in the manufacture of bricks, tiles, and slabs. September 22.
- 11285 J. W. Ludlam and S. Smith Harvey, London. Improvements in fire and sound proof flooring. September 22.
- 11462 C. Walton, London. Improvements in machinery for making and pressing clay and other material into bricks, tiles, and other forms or shapes. September 26.
- 11549 J. Parker, Glasgow. Improvements in the manufacture of fireclay bricks. September 29.
- 11790 J. Lewthwaite, London. Improvements in paving and the preparation of blocks to be used in part therewith. October 3.
- 11806 W. T. Timewell, London. Improvements in the manufacture of cement. October 3.
- 12118 G. Mingay Garrard, London. Improvements in machinery and apparatus for the manufacture of tiles. October 12.

## X.—METALLURGY, MINING, ETC.

- 10846 C. Bernard Holland, London. Improvements in annealing thin sheets and plates of iron and steel, and in furnaces suitable to be employed therein. Complete specification. September 12.
- 10910 A. J. Boulton, London.—Communicated by H. M. Pierce, United States. Improvements in the reduction of ores and obtaining the metal therefrom by the utilisation of waste gases from carbonisation of vegetable matter. Complete specification. September 15.
- 11067 W. Bealson, Rotherham. An improved process for recovering iron from waste fused iron. September 18.
- 11280 D. Davis, London. Improvement in means or apparatus employed in coating metal plates with tin, terne, or other metals or alloys. September 22.
- 11311 J. Robb, Dundee. Improvements in the methods of and composition for case-hardening metals. September 23.
- 11531 T. Williamson, Wishaw, N.B. Improvements in apparatus for treating iron and ores, etc., and for making steel therefrom. September 24.
- 11567 T. Williamson, Wishaw. Improvements in cupolas for smelting metals, ores, etc. September 24.
- 11602 R. Howarth Thwaite, Tranmere. A method of decarbonising, desilicising, dephosphorising, desulphurising fluid iron metal from blast furnaces or from cupolas, and apparatus therefor. September 25.
- 11647 W. J. Thompson, Liverpool.—Communicated by L. Imperatori, Germany. Improvements in the purification of iron by the basic process, and in obtaining by-products therefrom. September 25.
- 11699 J. S. Selton, London. Process and means for soldering aluminium. September 26.
- 11738 A. M. Clark, London.—Communicated by C. Cholat and F. Mercier, France. Improvements in and apparatus for treating and purifying cast-iron for the manufacture of iron and steel. September 28.
- 11624 E. R. Blundstone, London. The utilisation of waste tin and plate lead, and ternary plate. September 30.
- 11689 C. M. Pielticker, London. Improvements in the production of metal wire, tubes, and the like, direct from the molten metal, and in apparatus connected therewith. October 1.
- 11735 R. Evans, London. Improvements in machinery or apparatus for use in picking and swilling metal plates. October 2.
- 11798 O. Imray, London.—Communicated by L. Bondy, Austria. An improvement in the process of extracting wrought iron and steel directly from ores. October 3.
- 11802 A. J. Maskrey and W. Jones, Glasgow. Improvements in the manufacture of tin and ternary plates, and in coating other articles with tin. October 3.
- 11854 B. D. Healey, Liverpool. Improvements in the method of making apparatus therefor. October 6.
- 11873 H. W. Taynton, London. An improved bath for annealing steel. October 6.
- 12140 K. Kuiper, London. Process and compound for welding cast-steel or wrought-steel in bars without heating to a white heat with steel or iron, and for regenerating the welded steel. October 12.
- 12141 H. Brunner, Liverpool. Improvements in or relating to the treatment of phosphatic slags for the recovery of valuable materials therefrom. October 13.
- 12242 F. Huntington and M. Chiapponi, London. Improvements in effecting the extraction of silver from ores, alloys, or compounds containing the same. October 14.
- 12241 T. Childs Huntington and M. Chiapponi, London. Improvements in effecting the extraction of antimony from ores or compounds containing the same. October 14.
- 12265 A. Fehln, London. Improvements relating to the dephosphorisation of iron ore and to the production of phosphate of soda and phosphate of ammonia. October 14.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

- 11590 A. Twistleton Hall, London. Extracting oils from certain waste products. September 29.
- 11616 A. Wilkinson, London. Improved compounds or compositions for cleaning and polishing. September 29.
- 11726 W. Marriott and H. Marriott, Halifax. An improved process for improving or increasing the viscosity of oils. October 2.
- 11741 T. McGuffie, Liverpool. Improvements in apparatus for cleaning or soap into lengths. October 2.
- 12305 H. Livesey, London.—Communicated by Dr. Duncan, Russia. Improvements in liquid soap. October 15.

## XII.—PAINTS, VARNISHES, AND RESINS.

- 10838 A. J. Ward, London. Improved compound or body for the manufacture of pigments, applicable also to the purposes for which white or red lead is ordinarily used. September 12.
- 11129 G. L. Wigg, M. Steele, and W. J. Wigg, Liverpool. Improvements in plant or apparatus to be used in the treatment of residuals from copper works and chlorine manufacture to obtain pigments and sulphate of iron. September 19.
- 11170 O. Imray, London.—Communicated by Dr. E. A. Behrens, Germany. Improved process for bleaching and refining resins and similar substances. September 19.
- 1210 A. M. Clark, London.—Communicated by W. E. Harris, United States. An improved process for making metallic paint from lead. September 21.

- 11529 E. L. Kitchingman and A. Andrews, London. An improved waterproof and anti-corrosive composition suitable for coating ships' bottoms, and such like purposes. September 28
- 11543 G. W. Carr and J. Dickenson, London. An anti-fouling composition for protecting and preserving ships' bottoms and other submerged surfaces, applicable also for coating metal, wood, and other underground surfaces. September 28
- 11559 R. Oliver and J. H. Craven, London. A composition to be applied to bright metallic surfaces to prevent rust or oxidation of the same. September 30
- 12249 S. Baurer, Liverpool. A new or improved substitute for turpentine. October 11

### XIII.—TANNING, LEATHER, GLUE, AND SIZE.

- 11253 J. J. Flitch and J. R. Flitch, London. Improvements in emery wheels employed in the manufacture or preparation of leather. September 22
- 11281 J. J. Flitch and J. R. Flitch, London. Improvements in the means or apparatus for staking or graining leather, also for perching or softening the same. September 22
- 11854 A. Hutton, Accrington. Improvements in boiling size under steam pressure. October 6
- 11880 J. W. Davies, London. The industrial utilisation of leather waste. October 6
- 12302 H. England Howe, London. An improved method of rendering leather used for the outer soles of boots and shoes more durable and pliable and proof against damp. October 15

### XIV.—AGRICULTURE, MANURES, ETC.

- 10800 S. Deadman Cox, London. An improved process and apparatus for the treatment of coarse and inedible fish, broken fish, and the refuse from fish-curing establishments for manurial purposes. September 12
- 11669 R. Nicholls, London. Improvements in the mode of fixing ammonia and other gases for material and other purposes, and in apparatus employed therefor. September 29
- 11836 N. Barrett Fowler, London. An improved process of treating phosphatic earth or rocks for the purpose of rendering the phosphoric acid available as a plant-food. October 5
- 12231 J. Davies, Manchester. Improvements in and in the manufacture of fertilising compounds. October 11
- 12312 W. L. Lake, London. Communicated by G. Stollwerck, Germany. An improved method of and apparatus for causing the germination of barley and other cereals. October 15

### XV.—SUGAR, STARCH, GUMS, ETC.

- 10836 J. Ramsay Woodburn, St. John's, Canada. Pulverising sugar and other friable substances to an impalpable powder, called "Woodburn's pulveriser." Complete specification. September 12
- 10841 F. J. Lucas Tytler, London. A new material resembling gutta-percha, and the process for manufacturing the same. September 12
- 10951 A. A. Newton, London.—Communicated by P. C. Matherson and C. W. Torrey, United States. Improvements in the method of applying gum balata for insulating wires. September 15
- 10956 H. J. Haddon, London.—Communicated by L. E. Vial, France. Improved process for removal of gum from grass and plants. September 15
- 11618 W. Thomson, J. Mylne, and J. B. Allott, London. Improvements in apparatus for the expression of juice from the sugar cane. Complete specification. September 29
- 11671 J. Bagnall, Manchester. Improved means of dissolving vulcanised indiarubber and indiarubber compounds. October 1
- 11899 G. S. Baker, London. Improvements in machines for baking sugar, wafer cakes, and the like. Complete specification. October 6

### XVI.—BREWING, WINES, SPIRITS, ETC.

- 10949 E. Fielding, London. An improved apparatus for automatically regulating the flow of water and other liquids from coolers or like vessels. September 15
- 11935 W. S. Squire, London. Improvements in the manufacture of yeast. October 7
- 11970 W. L. Thompson, Liverpool.—Communicated by C. Ordonneau, France. Improvements in the production of alcohol. October 8
- 12035 G. G. Pickling, W. Hopkins, J. Dore and J. Dore, London. Improvements in the manufacture of vinegar. October 9
- 12036 G. G. Pickling, W. Hopkins, J. Dore and J. Dore, London. Improvements in the manufacture of spirits. October 9
- 12085 W. S. Squire, London. Improvements in the manufacture of yeast. October 10
- 12233 J. Hynes, London.—Communicated by H. Hnekmann, Bavaria. An improvement in the production of malt. Complete specification. October 11
- 12294 T. Webb, London. The principle of heating wash before entrance into the analysing column of distilling apparatus. October 15

### XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

#### (A) CHEMISTRY OF FOODS.

- 11189 J. D. Treharne, London. An improvement in the manufacture of tea by combination with the cocoa-leaf. September 26
- 11663 S. Fulda, London. Improvements in preserving fruit, vegetables, and analogous productions from decay, deterioration, and discoloration; and in preserving the sugar held in suspension therein from granulation. September 30
- 11881 J. A. R. Main and J. Dick, Glasgow. Improvements in apparatus for withering and drying leaves of plants, seeds, and analogous substances. October 6

#### (B) SANITARY CHEMISTRY.

- 10823 J. McIntyre, Junr., London. Improved appliances for disposing of sewage in bulk. September 12
- 11679 C. T. Kingzett, London. Improvements in the treatment and utilisation of sewage. September 14
- 11038 E. Davenport Latham, London. Improvements in means or apparatus for deodorising or purifying the gases issuing from sewers or other chambers, receptacles or channels. September 17
- 11115 E. Maxwell Dixon, Glasgow. An improved process for purifying refuse waters from mines, public works, and other sources. September 18
- 11255 G. K. Keeling, Epsom. Destroying bad smells and noxious gases in sewers, and efficiently ventilating them by the action of fire in flame or by heat-producing substances. September 22
- 11436 C. T. Kingzett, London. Improvements in the treatment and utilisation of sewage. October 1
- 11191 J. Scourah Randles, London. Improvements in the treatment of sewage, town refuse, and other foul substances. September 26
- 11716 M. Holt, London. Improved means for ventilating sewers, and deodorising sewage. October 1
- 11750 T. Mercer, Liverpool. Improvements in disposing of sewage so as to prevent the pollution of rivers, and in plant or apparatus therefor. October 2
- 11966 F. M. Knight, Halifax. Improvements in filters, and in the arrangement and combination of ingredients, or filtering medium employed therein. October 9
- 12206 E. Edwards, London.—Communicated by J. Buisson, France. Improvements in apparatus and appliances for purifying and cleaning water in canals or other watercourses. October 12
- 12311 J. Hanson, London. Process and means for disinfecting, deodorising, and purifying sewage and other foul waters or matters. October 14

#### (C) DISINFECTANTS.

- 10876 E. Burges Watson and H. Brock Fulton, London. Improvement in the preparation of hygienic and disinfecting substances, and use of the same, as candles, night-lights, and such like. September 14
- 11988 J. L. Sabunjee, London. Disinfecting and deodorising purposes, consisting of the combination of soap with permanganate of potash. "Crown perm. of pot. soap." October 8
- 12060 J. Foster and W. H. Bibby, Preston. An improved disinfecting, deodorising, and fumigating powder. October 10
- 12238 A. Boake and F. G. Adair Roberts, Stratford. Improvements in disinfectants. October 11

### XVIII.—ELECTRO-CHEMISTRY.

11153. E. J. Fraser, San Francisco. Improvements in treating wines and liquors with electricity, and in an apparatus for the purpose of carrying out the same. September 19
- 11224 M. Humm, London. Further improvements in electric baths. Complete specification. September 22
- 11632 T. J. Jones and W. H. Tasker, London. Improvements in the manufacture of plates or elements for voltaic batteries. September 30
- 11876 T. V. Hughes and C. R. Chambers, London. Improvements in the manufacture of carbon filaments for electric lighting. October 6
- 11879 J. Tatham, London. Improvements in the manufacture of metal-covered electrical conductors, and in apparatus therefor. Complete specification. October 6
- 12001 J. Swinburne, Brockley. Carbons for electric lamps. October 9
- 12040 F. S. Fowler, Haslemere. Sodio bichromate constant current electric battery. October 10

### XIX.—PAPER, PASTEBOARD, ETC.

- 10919 E. Davies, C. F. B. Birehall and A. Wood, London. Improvements in the manufacture of paper-pulp, and in apparatus therefor. September 15
- 11650 J. N. Young, Glasgow. Improvements in apparatus and methods for treating with chemical agents vegetable substances capable of yielding pulp for paper-making or other useful applications. September 29
- 11948 H. J. Rogers, Watford. An improved process for rendering the worn surfaces of water-lutes for straining paper-pulp, and apparatus used therefor. October 8

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

11258 D. D. Cattanach, London. Improvements in the method of and apparatus for the manufacture, distillation, and concentration of alcohol, hydrocarbons, and acetic acids. Complete specification. September 22

## XXI.—EXPLOSIVES, MATCHES, Etc.

10825 O. Imray, London.—Communicated by C. E. Birchel, Germany. Means of packing, storing, and applying liquid explosives. Complete specification. September 12

11065 G. H. Johnston, Lahardane, Mayo. Improvements in conical detonating sporting shells. September 18

11215 J. Cradon and P. Harding, London. Improved means and substances for producing an explosive agent, and the employment thereof for the working of engines for power purposes. September 21

11432 R. Punshon and the Patent Oxonite Company, London. Improvements in cartridges for blasting and other purposes. Complete specification. September 25

11419 J. Durlington, London.—Communicated by J. C. Newbery, Australia. Improved means for removing, destroying, or neutralising the fumes resulting from the use of nitro-glycerine for blasting. September 25

11899 W. Bruce Thomson, Wick, N.B. An improvement in the manufacture of matches. October 5

12228 Erskine H. B. Stephenson, Clapham. Improvements in the use of chlorate mixture in cartridges. October 11

## ENGLISH PATENTS PUBLISHED.\*

APPLIED FOR DURING 1884 AND 1885.

## I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

1885.

8527 W. R. Lako.—Communicated by J. W. Hyatt. Filtering apparatus. 1s

8866 D. Jarves. Retorts, and seals therefor. 6d

## II.—FUEL, GAS, AND LIGHT.

1881.

15323 F. J. P. Cheesbrough and E. R. Royston. Means of burning coal, etc., in furnaces; and apparatus for supplying and distributing such coal. 6d

1885.

8816 P. Jensen.—Communicated by J. E. Dery. Apparatus for the carburation of gas in railway or other carriage lamps and lanterns. 6d

9611 It. Dempster, jun. Centre valves employed in connection with gas purifiers. 6d

9773 H. J. Allison.—Communicated by C. C. Yeaton. Process for generating hydrogen gas. 6d

## III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

1881.

15821 J. McCulloch. Coke-ovens or retorts, and apparatus connected therewith. 6d

## SECOND EDITIONS.

13629 of 1884 H. W. Fenner. Distillation of coal tar, etc. 6d

13630 of 1884 H. W. Fenner. Heating of stills or boilers employed in the distillation of coal tar, etc. 4d

## IV.—COLOURING MATTERS AND DYES.

## AMENDED SPECIFICATION.

816 of 1884 L. Gans and J. M. Hoffmann. New colour yielding products. 4d

## V.—TEXTILES; COTTON, WOOL, SILK, Etc.

1884.

15877 W. T. Thompson.—Communicated by H. G. Bérard. The preparation and utilisation of peat fibre. 2d

\*Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d. ....	4d.
Above 8d., and not exceeding 1s. 6d. ....	1d.
" 1s. 6d., " " 2s. 4d. ....	1d.
" 2s. 4d., " " 3s. 4d. ....	2d.

## SECOND EDITION.

4984 of 1880 C. F. Cross. Treating jute, hemp, etc. 4d.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

1881.

13929 J. H. Johnson.—Communicated by E. Hermite. Improvements in bleaching, and apparatus therefor. 8d

## AMENDED SPECIFICATIONS.

1638 of 1881 T. Holliday. Producing azo-colours on cotton, etc. 4d

2346 of 1882 C. Holliday. Producing azo-colours on cotton fibre, etc. 4d

## VII.—ACIDS, ALKALIS, AND SALTS.

1881.

12306 J. Imray.—Communicated by E. Schaal. Converting petroleum and similar hydrocarbons into acids, soaps, and compounds of resin and ether kind. 6d

11333 H. Whitehead and R. Hodgson. Manufacture of salt from brine, and apparatus therefor. 6d

11419 P. M. Justice.—Communicated by L. E. Thomas. Treatment of alkaline chlorides. 2d

15393 S. Callard. Treatment of sulphate of iron. 2d

1885.

8511 H. Leplay. Decarbonating the carbonates of strontia and baryta; and apparatus therefor. 6d

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

1885.

7937 C. C. Thompson. Machines for making pottery, glass-ware, etc., from soft plastic materials. 6d

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

1881.

12803 E. Robbins. New compound chemical cements and concrete formations thereof for building. 6d

11321 P. M. Justice.—Communicated by C. Dietsch. Furnaces for burning cement and other substances, and linings therefor. 6d

11130 A. B. Joy and J. J. Lewen. Process for making imitation marble. 2d

11712 J. N. Moerath. Sanitary construction of fire and earthquake-proof houses, etc. 6d

15011 J. Thompson and J. H. Bryant. An improved artificial stone. 4d

15275 J. T. Welch. Utilisation of a waste product; and manufacture of bricks, tiles, etc., therefrom. 4d

16293 R. Smallman. Method of and apparatus for supplying lubricant to bricks during manufacture. 4d

1885.

8153 W. P. Thompson.—Communicated by R. Bosse and F. Wolters. Process for rendering cements hydraulic. 2d

8730 D. Crossley. Manufacture of porous or cellular bricks. 2d

8898 O. Hertrampf. Improvements in brick-kilns. 4d

9087 A. W. L. Reddie.—Communicated by T. Egleston. Method and compounds for preserving stone. 2d

## X.—METALLURGY, MINING, Etc.

1881.

11736 J. Riley and W. Crossley. Manufacture of steel; and furnaces for melting and treating iron, steel, or other substances. 8d

15197 P. Kirk. Ovens or furnaces for heating ingots or blooms, or for maintaining the heat thereof. 6d.

15504 J. J. Shedlock. Process and apparatus for the extraction of metals from their ores. 6d

15890 J. S. McDougall. Casting boilers and other vessels made of copper or of copper alloys with lead. 2d

15861 W. R. Lake.—Communicated by G. M. Westman. The reduction of iron or zinc ores, and apparatus therefor. 8d

1885.

510 J. Riley and W. Crossley. Furnaces for melting and treating iron, steel, ores, etc. 8d

6220 J. G. Laurie. Moulds for casting steel or iron compounds therefor. 6d

8392 W. P. Thompson.—Communicated by -- Osann. Purification of iron by the Thomas-Gilchrist process, etc. 4d

8661 W. Wood and M. H. Hurrell. Apparatus for refining copper and other metallic mattes. 6d

8819 W. R. Lake.—Communicated by W. H. Purdy. Purification of iron and steel. 2d

9169 H. Hall. Mode of coating metal plates or sheets with tin, lead, etc.; and apparatus employed therein. 4d

- 9496 F. y Pablos. Furnaces for melting. 6d  
 9556 H. J. Hadden—Communicated by E. Phillips and T. Jones. Preparation of the charge for zinc furnaces. 4d  
 9581 W. P. Thompson—Communicated by E. H. Cowles and A. H. Cowles. Process for obtaining aluminium and other metals from their ores, alone, or as alloys with other metals. 6d

#### REPRINTS AND AMENDED SPECIFICATIONS.

- 630 of 1856 H. Bessmer. Iron and steel. 8d  
 12182 of 1881 J. E. Atwood. Purifying molten iron or steel. 4d

### XI.—FATS, OILS, AND SOAP MANUFACTURE.

1881.

- 15031 C. Rumble and F. Sear. Preparation of oils used for lubricating wools preparatory to spinning. 4d  
 15332 W. P. Lake—Communicated by A. F. Le Myé. Purification of fatty or oleaginous substances, and apparatus therefor. 8d

1885.

- 9580 P. A. Newton—Communicated by S. Hornemann. Process for preserving crude animal fats. 2d

### XII.—PAINTS, VARNISHES, AND RESINS.

1885.

- 4313 H. J. Allison—Communicated by S. Dohmann & Co. Substance for lining or covering steam boilers, pipes, etc. 2d  
 7121 D. Melville and J. F. Whitney. Paints, coatings, or compositions for coating ships' bottoms or other submerged structures. 4d  
 8737 W. R. Lake—Communicated by J. P. Perkins. An improved paint or pigment. 4d

### XIII.—TANNING, LEATHER, GLUE, AND SIZE.

1881.

- 15607 B. Hunt. Curing hides or skins. 4d  
 15827 C. L. Royer. Process and apparatus to be employed in the steeping, liming, baiting, and tanning of hides. 4d

### XV.—SUGAR, STARCHES, GUMS, Etc.

1881.

- 11289 J. Sundstrom. Pans for evaporating cane juice and like solutions or liquids likely to boil over. 6d

1885.

- 6110 W. R. Lake—Communicated by W. T. Jebb. Manufacture of grape sugar or glucose. 6d  
 8786 H. J. Allison—Communicated by A. G. Day. Vulcanised kerite compounds, and processes for the manufacture of the same. 4d  
 8787 H. J. Allison—Communicated by A. G. Day. Vulcanised kerite compounds, and processes for the manufacture of the same. 4d  
 9326 W. R. Lake—Communicated by F. O. Matthiessen. Manufacture of hard sugar. 2d

#### SECOND EDITION.

- 815 of 1880 W. Morgan-Brown. Apparatus for moulding sugar. 6d

### XVI.—BREWING, WINES AND SPIRITS.

1881.

- 11694 T. Horsburgh. Machine for the preparation of finings for beer and other liquids. 8d

1885.

- 4937 W. R. Lake—Communicated by W. T. Jebb. Treatment of maize in the manufacture of spirits. 8d

- 9788 A. J. Boulton—Communicated by A. S. Bigelow. Pressure regulators for fermenting liquids. 8d  
 9847 P. M. Justice—Communicated by A. W. Billings. Manufacture of beer. 6d

### XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

#### (A) CHEMISTRY OF FOODS.

1881.

- 15778 E. Fontenille. Process for refrigerating and congelising liquids. 6d

#### (B) SANITARY CHEMISTRY.

1881.

- 13818 A. Angell. Manufacture of materials for use in the purification by filtration of sewage and other foul liquids and water, etc. 4d  
 11822 J. V. Johnson—Communicated by A. R. Leeds. Means for the purification of water. 6d  
 12810 J. W. Slater and W. Stevens. Preparation of an agent for use in the treatment of sewage and other putrescent matters, and treatment of such matters. 4d  
 16511 P. Smith and R. Wild. Means and apparatus for the purification and filtering of waters, sewage, etc. 6d  
 16592 J. W. Slater and W. Stevens. Purification of sewage by precipitation. 2d

1885.

- 900 F. M. Lyte. Purifying and deodorising sewage and other foul waters, and obtaining a useful product therefrom. 4d

### XVIII.—ELECTRO-CHEMISTRY.

1885.

- 8661 W. Wood and M. H. Hurrell. Apparatus for refining copper and other metallic matters by electrolytic and chemical actions. 6d

### XIX.—PAPER, PASTEBOARD, Etc.

1884.

- 12193 C. W. Knowles. Preparing sulphate of lime for use in paper making. 4d  
 11839 H. Vessier and A. Wilbaux. Cold process for the manufacture of paper pulps and bleached or unbleached textile fibres, and apparatus therefor. 6d  
 16891 T. H. Hodges. Machines for manufacturing paper, leather-board, and mill-board. 4d

### XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

1885.

- 8523 H. E. Newton—Communicated by G. Michaelis and W. T. Mayer. Manufacture of chloroform and acetic acid, or purified acetates. 4d

### XXI.—EXPLOSIVES, MATCHES, Etc.

1881.

- 11110 B. Brönes. Manufacture of explosive compounds. 4d  
 11737 E. J. Mills. Formation or preparation of explosive charges. 4d  
 16311 J. N. Heidenman. Manufacture of gunpowder. 2d

1885.

- 9022 H. E. Newton—Communicated by A. Nobel. Receptacle for hygroscopic explosives. 4d

### XXII.—ANALYTICAL CHEMISTRY.

1884.

- 15970 F. Lux. Method and apparatus for stating the specific weight of gases and vapours. 6d

# THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD  
FOR ALL INTERESTED IN CHEMICAL MANUFACTURES

No. 11.—VOL. IV.

NOVEMBER 30, 1885.

Non-Members 30. per annum; Members  
21. per Set; Single Copies 2 6.

## The Society of Chemical Industry.

### Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.

## COUNCIL FOR YEAR ENDING JULY, 1886.

President: E. K. Muspratt.

### Vice-Presidents:

Sir F. A. Abel, C.B., D.C.L., F.R.S.	Peter Griess, Ph.D., F.R.S.
Sir I. Lowthian Bell, Bart., F.R.S.	W. H. Perkin, Ph.D., F.R.S.
Alexander M. Chance.	Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
James Duncan.	E. C. C. Stanford.
David Gamble.	J. C. Stevenson, M.P.

### Ordinary Members of Council:

R. Forbes Carpenter.	S. A. Sadler, Ph.D.
Henry Doulton.	Sir Bernhard Samuelson, Bart., M.P.
John Evans, D.C.L., F.R.S.	Sir Chas. Tennant, Bart., M.P.
Ivan Levinstein.	Prof. W. A. Tilden, F.R.S.
Rudolph Messel, Ph.D.	John Williams.
B. E. R. Newlands.	
Thomas Royle.	

With Sixteen Chairmen and Secretaries of Sections.

### Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

### Honorary Foreign Secretary:

Ludwig Mond, 20, Avenue Road, Regent's Park, N.W.

General Secretary: Charles G. Cresswell.

### Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

## THE JOURNAL.

### Publication Committee:

The President.

Sir F. A. Abel, F.R.S.	F. Hurter, Ph.D.
Joseph Bernays, M.I.C.E.	Ivan Levinstein.
W. Lant Carpenter.	Prof. R. Meldola.
Prof. Frank Clowes, D.Sc.	Ludwig Mond.
George E. Davis.	C. O'Sullivan, F.R.S.
Prof. Dewar, F.R.S.	John Pattinson.
Prof. Chas. Graham, D.Sc.	Dr. W. H. Perkin, F.R.S.
Peter Griess, Ph.D., F.R.S.	Sir H. E. Roscoe, M.P., F.R.S.
D. B. Hewitt, M.D.	John Spiller.
David Howard.	A. Norman Tate.
Prof. A. K. Huntington.	Thomas Tyer.

Editor: Watson Smith, The Owens College, Manchester.

ASSISTED BY THE FOLLOWING STAFF OF

### Abstractors:

G. H. Beckett.	W. E. Kay.
D. Bendix.	A. J. King, B.Sc.
E. E. Berry.	D. A. Louis.
E. J. Bevan.	F. Machenhauer.
W. Dalrymple Borland.	Wm. Macnab, Jun.
T. L. Briggs.	W. G. McMillan.
C. Claus.	G. Harris Morris, Ph.D.
E. G. Clayton.	J. M. H. Munro, D.Sc.
Julius B. Cohen, Ph.D.	H. R. Procter.
C. F. Cross.	H. A. Rademacher.
A. R. Davis.	F. W. Renaut.
A. G. Green.	Sammel Rideal.
S. Hamburger, Ph.D.	James Taylor, B.Sc.
J. H. Hodgkinson.	F. L. Teed, D.Sc.
J. J. Hummel.	V. H. Veley, M.A.
C. C. Hutton.	Alex. Watt.
D. E. Jones.	Sydney Young, D.Sc.
Herbert Jones.	

## CHANGES OF ADDRESS.

Gerrard Ansell, 1 o Farnboro; 45, Courtfield Road, South Kensington, S.W.  
T. Burrell Bewick, 1 o Haydon Bridge; Hebburn-on-Tyne.  
F. Bohm, 1 o Dalkeith; 12, Charles Street, Edinburgh.  
Harry Chubb, 1 o Bayswater; 21, Lansdowne Place, Brighton.  
J. J. Coleman, 1 o West Nile Street; Ardara, Bearsden, near Glasgow.  
Wolf Ernst, 1 o Manchester; Oberlangenbielau, Schlesien, Germany.  
C. A. Fawsitt, 1 o Bellvale Chemical Works; Atlas Chemical Works, E. Nelson Street, Glasgow.  
H. M. Frear, 1 o Tollington Park; Hedgefield, Harpenden, Herts.  
R. J. Friswell, 1 o 5; 115, Darent Road, Stamford Hill, N.  
D. W. Greenbough, 1 o 9; 16, Mincing Lane, London, E.C.  
T. Guyatt, 1 o Wool Exchange; Ceara Gas Company, Limited, 9 Queen Street Place, London, E.C.  
J. Holloway, 1 o Servia; 7, Jeffrey Square, London, E.C.  
C. M. King, 1 o Bloomsbury Square; 3, Fernio Park Road, Hornsey, N.  
G. A. Liddle, 1 o Falkirk; Technical School, Princess Street, Manchester.  
W. C. Mackenzie, 1 o Edinburgh; Linlithgow Oil Company, Linlithgow, N.B.  
H. T. Mannington, 1 o Rumney Road; 60, Rawcliffe Road, Walton-on-the-Hill, Liverpool.  
W. G. McMillan, 1 o Jermy Street; Metallurgical Laboratory, King's College, Strand, W.C.  
J. L. Metcalf, 1 o Jarrold; Merrimac Chem. Co., 73, Kilby Street, Boston, Mass., U.S.A.  
B. Mohr, 1 o Battersea; e/o Rio Tinto Company, 30, St. Swithin's Lane, London, E.C.  
F. Rosicki, 1 o Frankfurt; 5, Quai Claude Bernard, Lyon, France.  
W. Johnston Saint, 1 o Aberdeen; Hess Strasse, 28, II, Munchen, Bavaria.  
A. W. Soward, 1 o Serjeant's Inn; 18, Scylla Road, The Rye, Peckham, S.E.  
G. G. Tomlinson, 1 o Runcorn; Rainham Ferry Vitriol Co., Rainham, Essex.  
A. W. Warrington, 1 o Strassburg; 3, Bahnhof Strasse, Gottingen, Hanover.  
W. J. Williams, 1 o Seacombe; e/o Col. J. V. Dunne, 305, Walnut Street, Philadelphia, Pa., U.S.A.

## CHANGES OF ADDRESS REQUIRED.

A. C. Lee, 1 o Johnson & Co., Canterbury.  
H. Peile, 1 o Middleton-one-Row, near Darlington.  
J. H. S. Wildsmith, 1 o 121, Upper Kennington Lane, S.E.

## LIST OF MEMBERS ELECTED, NOVEMBER 23rd, 1885.

Sir H. W. Acland, K.C.B., F.R.S., Ratcliffe Library, Oxford, and e/o Messrs. Dulac & Co. 37, Soho Square, W.C., librarian.  
Edwin M. Bailey, Royal Bank of Scotland, Ardrossan, Ayrshire, chemical student.  
H. C. Cieshank, 88, King Street, Manchester, chemical merchant.  
G. W. Cooke, Bryn Hall, Bangor, North Wales, slate-quarry owner.  
Joseph Dixon, Spring Grove, near Sheffield, paper manufacturer.  
Edward Eastwood, Tunnel Soap Works, Wapping, E., soap manufacturer.  
T. J. Flynn, Shepley Mills Linoleum Co. Limited, Guide-bridge, near Manchester.  
Tamesasa Haga, Imp. Coll. Engineering, Tokyo, Japan, chemist.  
C. Felce Hare, 23, Beaufort Road, Clifton, Bristol, oil and paint manufacturer.  
Ern. W. Harvey, Thornlie Park Villa, Wishaw, N.B., metal lurg. eng.  
Jno. Henshaw, Brook Street Soap Works, Manchester, soap manufacturer.

Michitada Kawakita, M.E. Imp. Coll. Eng. Tokio, Japan, chemist.  
 Arthur Kenyon, 59, Camden Grove, Peckham, S.E., brewer.  
 W. T. Liddle, 387, Blackburn Road, Church, Lancashire, chemist.  
 Walter T. Lye, The Firs, Luton, Beds., straw-plait dyer.  
 E. W. A. Mayhew, High Street, Fremantle, Western Australia, and Co. "Burgoyne's," Coleman Street, E.C., manufacturing chemist.  
 H. R. Nason Ph.D., M.D., LL.D., Troy, N.Y., U.S.A., professor of chemistry.  
 T. Nishigawa, H. Go Bancho Koji Machi, Tokio, Japan, chemist to paper mills.  
 Tetsukichi Shimidzu, M.E. Imp. Coll. Eng. Tokio, Japan, chemist.  
 F. Wallis Stoddart, Western Counties Lab., Bristol, analyst.  
 Chas. Thompson, St. Ninian's House, Leighton Crescent, Brecknock Road, N.W., demonstrator of chemistry.  
 O. W. G. Trenon, Helston Lodge, Lower Addiscombe Road, Croydon, chemist.  
 Alf. Waché, 19, Rue Reaumur, Paris, chemical student.  
 Jas. Welsh, Clayton Mount, Newton Heath, near Manchester, printworks manager.

ERRATUM.—In the last number of this Journal, page 576, 2nd column, line 11, the price of bromine is stated as 35s. per lb. Read 25 cents, or 18. 9d. per lb.

## London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

Committee:

Sir F. A. Abel.	I. Messel.
H. E. Armstrong.	B. E. R. Newlands.
W. Lunt Carpenter.	B. Redwood.
W. Crowder.	T. Boyle.
C. Graham.	John Spiller.
S. Hall.	G. C. Trewby.
A. K. Huntington.	J. Williams.

Local Sec. and Treasurer: Thos. Tyrer,  
 Garden Wharf, Church Road, Battersea, S.W.

MEETINGS, SESSION 1885—86.—First Monday in each month (unless otherwise indicated).

### ORDINARY MEETINGS.

First Monday in the Month, at 8 p.m.

December 7.—Dr. P. F. Frankland on "Some Aspects of Filtration and other Methods of Water Treatment." Dr. F. L. Teed—"Note on the action of Calcium Carbonate on Solution of Ammonium Chloride."  
 January 1, 1886.—Mr. G. E. Davis, F.I.C.—"On the Enrichment of Coal Gas by certain Hydrocarbons." Mr. C. T. Kingzett—"Notes on Russian Turpentine."  
 February 1.—Mr. Gustav Bischof—"Notes on Dr. Koch's Water Test." Mr. J. W. Westmorland, A.R.S.M.—"The Estimation and Valuation of Copper Ores and Products for Commercial Purposes."  
 March 1.—Mr. Beaverton Redwood, F.I.C.—"Viscosimetry." Mr. T. B. Lightfoot, M.I.C.E., M.I.M.E.—"Ice Making and Cooling Machinery."  
 April 5.—Professor Unwin, M.I.C.E.—"The Principles and Methods of Testing Cementing Materials."  
 May 3.—Messrs. Menzies and Beckett—"The Treatment of Water for Technical Purposes."  
 June 7.—Dr. Meynott Tidy—"Chemical Treatment of Sewage."  
 July.—Annual Meeting at Liverpool.  
 Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held Monday, October 26, 1885.

MR. D. HOWARD IN THE CHAIR.

## HEATING REGENERATIVE GAS-FURNACES BY RADIATION FROM FLAME.

### DISCUSSION.

THE CHAIRMAN commenced the proceedings by referring to the loss the Society had sustained by the death of the former Chairman of the London Section—Mr. Walter Weldon, F.R.S.—to whose memory and labours he paid a fitting tribute. Passing to the subject which was to occupy the attention of the mem-

bers that evening, he said they were exceedingly fortunate in having amongst them the distinguished author of the paper which was heard with so much pleasure at the annual meeting of the Society in July; and he hoped the result of the discussion would be to throw some light on the practical application of the physical questions involved in the production of heat, which were of no little importance in these days of modern chemistry. He could not help thinking that they hardly appreciated how very much chemistry had to learn from the physicist—how much, in particular, with regard to the question of the full development of the force stored up in coal they had yet to learn. To say that in these days there was nothing more important than real economy in fuel was a mere truism; but, unless they could call in the aid of such men as Mr. Siemens, it was difficult to see how the resources which Nature had placed at their disposal could be thoroughly developed. They knew the theoretical power which ought to be obtained from 1 lb. of coal, and they also knew (or perhaps a great many did not know) how much they fell short of this in practice in furnaces and boilers. There was before the physicist a vast field of improvement in the economy of coal, which might bring about a revolution quite as great as that produced by Watt's discovery of the steam-engine. He had great pleasure in asking Mr. Siemens to make any preface remarks he might feel inclined to offer; and he hoped all the members had taken an opportunity of carefully studying the paper, and would be fully prepared to discuss it, and show their appreciation of the importance of the problem before them.

MR. F. SIEMENS: I may commence by explaining that, when I first altered the chambers of my furnaces so as to work by radiant heat, I had no scientific motives in view; I simply wished to improve the manner of working and the capabilities of my factory. I looked at the matter with the eye of a manufacturer who wanted to increase and cheapen production, and to improve the articles produced; to solve scientific problems was no part of my intention at that time. That is the reason why I worked this new system in my own establishments abroad for some time before publishing it. After having made considerable progress in the development of the invention at my Dresden glass works, heavy duties were imposed on glass entering Austria, and as I exported a large proportion of the products of my Dresden works to that country, I was compelled to construct new works in order to avoid paying the duty. I selected Neusattel, near Karlsbad, in Bohemia, as the locality for those works, and however regrettable it might be to me, from a manufacturer's point of view, to have to invest capital in their construction, they afforded me the opportunity of making further trials, as it is easier to design new furnaces to effect a special purpose than to alter old ones. These works came into operation in 1878, and although I obtained from the new furnaces improved results upon those obtained at Dresden, I did not yet see my way to take out patents, owing to the circumstance that the conditions involved in the new method of heating, as at that time practised, could only be explained from a scientific point of view, and that German patents are strictly limited to features of construction. Moreover, I desired to make further trials, and I felt sure of keeping the secret of the invention to myself, owing to the difficulty which would be experienced in discovering it from the outward appearance of a furnace. I was confirmed in this view by the consideration that the principles involved in my new furnace were directly opposed to the old notions of furnace construction and of combustion. But a few years later, after the gradual enlarge-

ment of my new works at Neusattel, and the construction of additional furnaces at Dresden and Doehlen, the experience obtained enabled me to mature my invention and to determine the features of construction essential to its success. This was about the time I took upon myself to carry on the work of my late brother, Sir William Siemens, and I determined to apply for patents and to publish the invention. The first memoir on the subject was the paper which I read before the Iron and Steel Institute, at Chester. On that occasion I kept strictly to the practical details of the furnace, leaving out theoretical questions altogether. I explained how, in order to bring about radiation, the flame was conducted through the furnace in such a way that it does not touch any part of the surface, either of the roof, sides, ports, or bottom, but is able to radiate heat freely in the chamber, and then go through the ports into the regenerators to deposit its remaining heat there by contact. In the first part of the operation the flame acts by radiation, in the second part by contact; this, as is shown by innumerable publications and descriptions of furnaces and systems, is the contrary of what has always been observed; there has always been a tendency to contract furnace chambers to the smallest possible size, and to bring the flame into contact with the side of the furnace and with the material to be heated; and where, on rare occasions, an exception has been made on account of the material which was to be operated upon not admitting, for some reason, of being touched by the flame, it was always explained why such a divergence from ordinary practice was necessary. During the discussion of my paper at Chester I described the theoretical part of the system, which has been taken up with great interest, most of the technical journals, and the writers for those journals, approving of it, some, however, having objected to it; and what surprised me was, that the principal objections were made on theoretical grounds, and ignored all the practical results, treating my work as mere scientific conjecture. On the whole, I am not at all dissatisfied with the opposition that has been raised against my new method of heating, and it was only what I could expect, as it interferes with many well-accepted arrangements and old-established views which will not be readily given up, although it can be shown that by supplanting them great practical results are obtained. Some have objected against the system that it is not new, because high roofs have been in use before. To this it may be answered that there is hardly anything new in form; the only question is with what intention a certain arrangement has been chosen. If, as has been the case, anyone says that he has seen furnaces with high roofs before, I can only ask him for what purpose such high roofs were adopted. There are various reasons which may induce a furnace builder to construct a high roof; besides, a high roof forms no part of my system, but it is only one of the means I employ to conduct the flame through the furnace-chamber in such a manner that only radiant heat comes into action there. If the high roof has not been selected for that purpose, and the flame continues to strike down on the bed of the furnace, such furnaces cannot be considered as constructed according to my system. I am still awaiting the production of any publication which shall show that furnace-chambers have ever been constructed in the same manner and for the same purpose as those described in my paper. Hitherto nothing has been brought forward to prove that my new method of constructing and working gas-furnaces has in principle been anticipated, even in the slightest degree. The scientific grounds on which objection has been made to my system were simply with regard to the laws of the dissociation of flame. It was maintained that it was

utter nonsense to talk of accumulating heat in the way I described, because, when a certain temperature was arrived at, dissociation set in, and at such a high temperature no further combustion took place; so that however perfect the combustion might be, no advantage would be gained, because a certain temperature could not be exceeded. I could only set against this argument the fact that I was always able to increase the temperature, the only limit being the heat-resisting power of the material of which the furnace was built; so far I have not found any material sufficiently refractory to withstand the intense heat that may be obtained in the radiation furnace; but I think that further experiments I am making with that object in view will result in the production of a material more suitable for furnace building than any hitherto used. I have found that when furnaces, on the other hand, had small chambers, and the flame played directly on the sides, the inner walls, the arch, and the hearth, then certainly the heat did not rise to the same extent. This is a state of things which some call "dissociation;" but I attribute it to "imperfect combustion," brought about by the action of the surfaces. When the flame strikes in the immediate neighbourhood of the arch of a furnace, or of any solid material, the combustible gases cannot burn—they want elbow-room, as it were. After studying the question of dissociation, and the experiments which had been made, I came to the conclusion that the whole theory of dissociation of flame is not yet perfectly developed, or at least that no system of furnace construction can be fairly criticised from the dissociation point of view. I found that dissociation in an open space can only occur at a very intense temperature—so high, in fact, that we cannot reach it—and consequently it need not enter into any of our calculations of furnace building, always supposing that there is free space for the gas to burn in. On the other hand, most of the apparent cases of dissociation recorded admit, to my mind, of another explanation. It is the indirect influence of the inner surfaces of the apparatus employed which, in many cases, accounts for the appearance of dissociation. There are some experiments which prove this very clearly. I shall only refer to the experiments of eminent authorities, from which you will see that dissociation is always brought about by surface action. Bunsen established dissociation in the following manner:—He filled a tube with carbonic oxide and oxygen just in the right proportions to burn. He ignited it by some means, and produced an explosion; but he found that only one-third of the gases took part in this explosion, and the other two-thirds remained unburnt. He obtained, however, a temperature (according to his calculation) of  $2400^{\circ}\text{C}$ . Now, Bunsen relates that when he allowed a certain interval to elapse, so that the tube might cool down perhaps to  $1000^{\circ}\text{C}$ , he could produce with a portion of the remainder of the gas another explosion; the heat rose again, and the limit of explosion was again touched, so that no further combustion could take place. After cooling it a second time he produced a third explosion, and found that most of the combustible gases were consumed. Now, Bunsen says—and it seems very plausible—that, at a temperature above  $2400^{\circ}\text{C}$ , the gases do not enter into combustion, and that if you could raise the temperature higher by some artificial means, dissociation would set in, and the burning gases would separate. I would offer another explanation of these results, and this I am bound to do, to agree with the facts of combustion which I have proved to exist in regenerative furnaces worked by radiation. I am of opinion that only one-third of the gases filling the tube had sufficient space in which to burn; the other two-

thirds were too near the circumference of the tube; they adhered to the sides, or struck on the sides, and consequently remained unburnt. When, however, a short time had elapsed, the gases mixed again by diffusion; the portion next the sides moved towards the centre of the tube, and then another explosion could take place. Again waiting for this diffusion to do its work a second time, a third explosion was possible. According to this theory, the heat had nothing to do with the result, but only the influence of the sides. Now, to prove the correctness of my inference, I would refer to the experiments on dissociation of some Russian scientists, Menschutkin and Konsvalow, which quite confirm my views; they found that if the vessels in which the experiments were made had roughened surfaces, or contained sand, asbestos, or ground glass, there was considerable dissociation. This just proves what I have said, that where there is a rough surface the combustion is more difficult, more sluggish, and cannot take place so readily. I wonder these gentlemen call this action "dissociation," as it would appear to be the influence of surfaces that brought it about. To some extent this is also corroborated by the evidence of the father of the dissociation theory, Deville. In his book he describes innumerable experiments which he made to prove dissociation by heat; but he says, at the same time, that he requires porous tubes. He has to employ material of various kinds, which he puts into the tubes he uses, and shows that much depends on the material he employs. Besides, there is a very curious circumstance which goes still further to prove what effect surfaces have. Deville proved dissociation of carbonic acid by producing carbonic oxide and oxygen; but he also dissociated carbonic oxide itself, producing carbonic acid and carbon. So that two directly opposite effects are supposed to be produced by the same means—viz., by the action of heat; but it seems quite impossible to conceive how heat could at one time produce dissociation of one kind, and at another time of another kind; at one time dissociate carbonic acid, with the production of carbonic oxide and oxygen, and at another time dissociate carbonic oxide, and make carbonic acid and carbon. There are other scientific men who have experimented on dissociation; for instance, Victor Meyer, who dissociated water by dropping melted platinum into it. Melted platinum has a high temperature, and he thus produced steam which was dissociated into oxygen and hydrogen. But the influence of platinum on hydrogen is well known; it condenses it, even so far as to set fire to it. Why, then, should it not be instrumental in bringing about dissociation? The same thing occurs, to a less degree, when steam is passed through a platinum tube heated from the outside. Meyer (who, by the way, disputes the correctness of Menschutkin's results) thus obtained signs of dissociation; but, of course, the heat inside the tube when heated in this way will not be very great, and the steam passing through the tube would not have much heat imparted to it, so that in this case the heat would be so small, that in spite of the presence of the surface of platinum, he only had traces of dissociation. He also obtained traces by passing carbonic acid through a platinum tube. It must not be forgotten that platinum has also an influence on oxygen; it is oxidised, and consequently it may be instrumental in bringing about this dissociation. It seems to me that it must be so, because the heat conducted to anything passing through a tube which is heated from the outside is so small in quantity and intensity as not to be sufficient in itself to produce dissociation; the heat, in fact, would be of a lower temperature than any flame we have. All that I have said tends to show, there-

fore, that in furnace building dissociation may be left almost entirely out of consideration. It is only in cases where furnaces have very small chambers, so that the flame comes in contact with surfaces, that the appearance of dissociation might take place. I have given you my theory of dissociation, and brought it into harmony with my system of furnaces, and I think I am right in my view. But I do not pretend to be an authority on scientific matters, and would rather leave these questions to scientific authorities to determine the right theory. Here (referring to a model) is a furnace which is supposed to be a portion of a boiler flue worked by radiation. The flame passes through the boiler tube without touching it, and gives its heat to the boiler by radiation. In returning, the flame has to play on the surface of the boiler, and heat it by contact. As long as the flame is in a state of active combustion, it should not touch any surface; but, after the combustion is completed, contact is necessary. I have such boilers at work; they do not make a particle of smoke, and there is a great saving of fuel, of the boilers themselves, and of furnace material. (Mr. Siemens then explained various diagrams, exhibited when his paper was read, showing the construction of furnaces; and also showed the regenerative gas stove, which he exhibited and described at the meeting of the Gas Institute in June last.) Mr. Siemens then went on to say that an English fire-place is a very healthy arrangement, as it gives out radiant heat only. The only drawbacks to it are the smoke produced and the mess of coal, ashes, and soot, which ought to be done away with. The stove exhibited in action is made with the view to increase radiation of heat; it is supplied with a regenerative burner producing intense heat, and consequently it has great heat radiating power. Gases which have passed through the combustion stage act in much the same way as air, which cannot radiate out heat if it is ever so hot, because it is not a solid body. I can give you the results of some experiments which I have made with my brother, Dr. Werner Siemens, who heated air to try whether it would radiate light, and it does not, even if ever so hot. If any light is radiated it is simply from particles of dust in the air, or some other solid matter which is suspended in it. These radiate heat, and emit light when heated, but air itself does not do so. In the gas-stove exhibited, the products of combustion going down behind the flame pass into a regenerator, which heats the air that is brought up for combustion. The heat of the products of combustion is given up by contact to the regenerator, which heats the air by contact, and the hot air, in combining with the gas, produces the intensely-hot and bright flame which has such high heat and light radiating power, thus the remaining heat of the products of combustion is not lost, but is used to increase the heat radiating power of the flame. This stove burns something like 14 cubic feet of gas an hour, about the consumption of two to three ordinary burners, and for any moderate sized room this would be quite sufficient. If this stove were used it would entirely abolish smoke, and, being a gas-stove, there could be no ashes or soot produced.

The CHAIRMAN said the main practical question involved was how far radiant heat, or how far direct-acting flame was the more economical. On the other hand, there was the very interesting scientific question of the heat—the dissociation of flame; both of which points were well worthy of very careful consideration.

Professor ARMSTRONG said he had been greatly interested in hearing Mr. Siemens's remarks on the subject of dissociation, and felt very much inclined to take his side on this question. Attention had

been specially called to the influence which surfaces had in promoting dissociation. He certainly agreed with Mr. Siemens in thinking that probably many of the results which had been obtained were not purely heat effects, but that the surface employed had a great deal to answer for. With regard to the experiments referred to, in the first place, one was inclined now to look at this matter from a somewhat different point of view from that taken by Bunsen, since the publication of Mr. H. B. Dixon's work, which had clearly shown that the combustion of carbonic oxide and the behaviour of carbonic oxide and oxygen mixtures were largely dependent on the amount of water vapour present; so that conclusions drawn from such experiments as those made by Bunsen were practically not of any great value. With regard to the Russian experiments referred to, there was also some doubt, as they had been altogether called in question by Victor Meyer. One would like to hear some discussion on the very important question raised as to the effect of incandescent solid matter. If he understood Mr. Siemens rightly, the whole radiant effect of a flame was due to the presence within it of incandescent solid particles. This certainly was a most important point. If the efficiency depended, as had been maintained, on obtaining the chief amount of heat-energy in this way, then the point to which attention had been called was of extreme importance; the method of heating described entirely depended on the acceptance of this theory. With regard to the beautiful burner exhibited, he could not help remarking that Mr. Siemens must do something before he introduced it into London. He must first help to get a better gas supply; for, practically, at the present time, they were not in a position to use such burners, because the Gas Companies supplied gas of such quality that the first thing it did was to close its own passage-way. The South Metropolitan Gas Company especially were, at the present time, engaged in trying to block up their own mains. They were using ordinary Newcastle coal alone, and the result was that the gas was highly charged with naphthalene, but contained nothing to prevent it being deposited; and, on cold weather coming on, it rapidly stopped up the main and service pipes.

Mr. SIEMENS said it was quite correct that, in his opinion, radiation only proceeded from the free carbon in the flame. If there was only carbonic oxide gas or hydrogen in the flame, there would be little radiation; but even these gases should be burnt in an open space before being brought into contact with surfaces to avoid loss of effect, as when flame acted directly on brickwork, combustion was very imperfect. What was called "dissociation" would set in; but, according to his views, it would be imperfect combustion. To work a furnace by radiant heat to the best advantage, fuel containing the largest proportion of hydrocarbons, or, in other words, gas from the coal generally met with, should be used.

Professor HUNTINGTON said this subject seemed to divide itself into two questions—the practical aspect, or the heat-value of Mr. Siemens's furnace, and the theoretical question as to where the maximum limit of heating power was to be found. With regard to the theory, he did not think it was worth very much. True theory could only be the result of perfect practice; and when they had the practice perfect it was time to formulate a theory. At present they had not sufficient results to enable them to formulate a theory; they could only frame working hypotheses to give direction to further investigation. With regard to the practical aspect of the question, it was difficult to carry on any discussion at present, because these furnaces, although being worked on a

very large scale, were in the hands of Mr. Frederick Siemens and those associated with him; and, in order to discuss the matter, it would be necessary that they should be working in different places under different conditions, so that they might be compared. He could only say, in regard to the furnaces themselves, that he saw them working about a year ago at Landore, and was greatly struck with them. The first thing about them was their remarkable simplicity, which would give them a much longer life. The work could be carried on without stopping to make repairs. As far as he could judge, the temperature obtained in the Landore furnaces was all that Mr. Siemens claimed. All furnaces were heated partly by radiation and partly by contact. Mr. Siemens's furnace was an improvement in the direction of heating by radiation. With regard to dissociation, it always appeared to him that the results obtained by Bunsen and Deville were very far from finality. If he recollected rightly, they obtained the commencement of the dissociation for the aqueous vapour, for carbonic oxide, and for carbonic acid between  $1100^{\circ}$  and  $1300^{\circ}$  C.; but he had never yet heard that anyone had claimed to have ascertained the point at which complete dissociation took place. They had it on the authority of Deville that, when hydrogen was burnt in an equal volume of oxygen, he obtained  $2500^{\circ}$  C. under the conditions of the experiment; but this, so far as he (Professor Huntington) was aware, was the only statement on the point. No one had given anything conclusive to show the point at which the whole of the gases would undergo dissociation. In fact, Deville had pointed out that the tension of dissociation was to be defined on parallel lines with vapour tension, and that just as water would be converted into vapour at ordinary temperatures, so gases would undergo dissociation at a point very much below the temperature which would be obtained by the combustion of the constituents. It was evident, therefore, that the subject was quite an open one.

Professor ARMSTRONG said it was very interesting, in connection with this subject, to recollect that it had been shown that at a temperature not far below  $2000^{\circ}$  C., carbon dioxide did not undergo any change, whereas carbon monoxide decomposed to an appreciable extent, and water also was decomposed below this temperature.\*

Dr. SQUIRE said Mr. Siemens had called attention to the fact that the surface in a tube over which gases were passing favoured dissociation. He would remind him that surface in the same way favoured combustion. It was very well known that certain substances (such as oxide of iron, clay, and some others) would promote the combustion of particular gases; so that there was at the same time a cause which would produce dissociation and also combustion. With regard to the temperature, for example, at which oxygen and hydrogen were dissociated, one could hardly expect to fix this, because, in a great many cases, the presence of the gas affected the decomposition of the material. He had himself found that it was perfectly impossible to saturate ordinary air with sulphur; as the two could not be made to combine. A certain percentage of sulphurous acid could be arrived at; but one could not get any further, however high the temperature was raised. But the presence of other gases very much affected the tendency to combine, or the decomposition of the

\* Note added during revision by Dr. Armstrong.—I find that I overstated the temperature, which was only about  $1700^{\circ}$ . It is noteworthy, however, that, whereas, according to Meyer and Langer, carbon dioxide passes unchanged through a platinum tube at this temperature, Meyer and Zúblin have confirmed Deville's observation that it is decomposed to an appreciable extent at  $1300^{\circ}$  when passed through a porcelain tube filled with fragments of porcelain.

substance in question. If gases acted more or less as vacua to one another, then also the products of decomposition, as well of decomposition going on, would materially affect the temperature of dissociation. One obtained a certain result, and could not go any further at this temperature. If the temperature went a little higher, there was a sort of partial decomposition. He would suggest to Mr. Siemens whether it was absolutely certain that his theory of the effect of contact was absolutely proved under these circumstances.

Mr. E. Dowson said the question of heating boilers in this way by gas was very interesting, and the chief point appeared to be that the flame should not be allowed to come in contact with the boiler-plates, because this lowered the temperature by reason of the contained water; and they were told that this imperfect combustion and consequent loss of heat might be avoided by not letting the flame come in contact with the plates, and by using only the radiating power of the flame and the conducting power of the products of combustion. In principle this was doubtless correct; and the more nearly it could be followed in practice, the less loss of heat would there be, and the less nuisance from smoke. At the same time it must be remembered that the exigencies of construction and space required the greatest heat to be produced with a minimum surface exposed; and he had some fear that such a system as this could hardly be applied with advantage where such a concentration of heat effect was necessary. At any rate, he should be glad to hear Mr. Siemens's views on this point. Where a boiler was heated by gas drawn from a producer, there was no incandescent mass of fuel, but only the flame and the products of combustion to heat the boiler with; and it was, therefore, no doubt of the greatest importance that the best possible treatment of the flame should be correctly understood. They had to seek not only a flame of high radiating power, but also one capable of giving up its heat by conduction rather than by radiation. With this point in view, he would ask Mr. Siemens if he would kindly state whether he had obtained any economic advantages by applying his system to a boiler of ordinary construction. It would be extremely valuable if he had data derived from experiments on one boiler with the three systems of firing to which he had referred—(1) heating with solid fuel, (2) heating with gaseous fuel with contact, and (3) heating with gaseous fuel without contact.

Mr. SIEMENS said so many questions had been asked that he could hardly answer each separately. He could only say that for the last ten years he had used no other fuel than gas, and that the results obtained by the new method of heating are to be compared with those formerly obtained by the old method of heating by gas. There was always a great advantage in using gas as fuel if it were well managed; there was not only the saving in fuel, but also a very great saving in labour. There was also great economy in the wear and tear of furnaces and material of all kinds, but if they worked with gas they required to use it constantly. If it was employed in the daytime and not at night, there would be a loss, but if there was application for the gas both during day and night, it was very economical. He only used radiant heat as long as the flame radiated out heat; as soon as the visible flame ceased he brought the gases into contact with the surfaces he wanted to heat, for when combustion ceased, then the gases might be brought into contact with anything as they had no injurious effect. It was only the active flame which injured surfaces, not by its heat, but by the excessively rapid motion of the gases. Surfaces upon which a flame played were always roughened, and he took

this to prove the destructive action of the flame which no material could stand for any length of time. In attempting to use an active flame, and to abstract the heat by contact, a double injury was inflicted; the heat that might otherwise be produced was lowered, and the material with which the flame was brought into contact was destroyed, besides smoke being produced. In using a flame which had little or no radiating power in it there was the same need for a combustion chamber, for the flame should not be allowed to play at once against surfaces or brickwork, as then there would be imperfect combustion. It was the surface itself, not alone its cooling influence, which was injurious to the flame. In heating a boiler it was still necessary, even if they had fuel which did not radiate heat, to provide a combustion chamber.

Mr. FLETCHER said there could be no doubt about the efficacy of the radiant heat produced from combustion; for all furnaces were, as a rule, heated entirely by radiant heat. He thought, therefore, they would all support Mr. Siemens's view that it was radiant heat after all, which was employed generally when a very high temperature was required. It was chiefly where a low heat was required (such as in a boiler) that the heat of conduction was mainly used. If Mr. Siemens had made experiments on any particular fuels, and could tell the meeting the difference between the heating power of fuel used where the bottom heat only was employed, and where it was so burnt as to develop more particularly the radiant heat, and could give them some figures showing the amount of water evaporated per lb. of coal burnt under the two systems, it would, he thought, be very valuable.

Mr. SIEMENS said he had not paid very much attention to the subject of boilers, and could not give any figures. He had fired his boilers on the new system because he was convinced that it would be a great advantage, and found it was so, for he used from 20 to 30 per cent. less fuel to do the same work as before; and the boilers worked more regularly, had a longer life, and required much less attention. With regard to heating by radiation in chemical furnaces he had already stated that there were cases where radiant heat was used for some particular purposes; but it had been explained in these cases why it was so used, and even then, such furnaces did not work fully by radiation as he had explained it. In the way furnaces were generally constructed the flame struck against anything, and this was just what should be avoided.

Mr. MACTEAR said it occurred to him that there was one furnace especially in which the principle of radiation was carried out very fully—viz., the old-fashioned regulus furnace which existed on the Tyne as far back as 1822. In this furnace the space above the main part to be heated was very high, but the bridge also was very high, and had a narrow slit, and the flame came over. Being a very small body of flame compared with the mass of the furnace, it floated about almost like a cloud. There was very little draught in the furnace, and the heating was practically all done by radiation from the flame. Mr. Siemens seemed to have taken this principle, and expanded it enormously; and there was no doubt the results he had obtained were of very great importance. He (Mr. Mactear) thought, however, that a good deal of this was due to one fact which had not been touched upon, and that was that for a given consumption of fuel he had enormously increased the size of the combustion chamber. Consequently, the speed of the passage of the gases through this chamber was much retarded, and a longer time given for the combustion of the

gas in the chamber itself. This seemed to him a very important matter, which tended much to the success of the system. With regard to Bunsen's experiments on dissociation, if the question depended, as Mr. Siemens thought (and probably with reason), on the effect of surfaces, and if the combustion of a gas ceased at a certain point, owing to the amount of surface exposed, it would seem a comparatively easy matter to repeat the experiments with tubes of different diameters, and see whether the amount of dissociation differed. This would probably show the effect of surface contact.

Mr. SIEMENS said Mr. Mactear spoke in the same way as Mr. Deville had done. He obtained dissociation, but he wanted all kinds of surfaces to bring it about; and as long as surfaces were wanted there was no saying what influence they had. With regard to the heating of boilers, he did not think the production of steam would be less with radiant heat, but rather more; but if the flame struck against the sides or other surfaces a considerable amount of heat would be lost, because they would get covered with soot, which the heat could not penetrate. Radiant heat, especially with a large body of flame, had always a very powerful effect, because flame radiated heat from the inside as well as from the outside, not like a solid body, which only radiated from its surface. The slowness with which the flame passed through the furnace chamber had a very beneficial effect, as Mr. Mactear had stated, as it allowed the radiant heat more time to act, whilst as regards the heating by contact which took place afterwards, this should be more effective than in an ordinary solid fuel furnace, on account of the higher initial temperature of the flame.

Mr. Dowson said he thought Mr. Siemens had somewhat modified his original proposition. It now appeared to be that the extra space given in the new type of radiation furnace over the space required on the old type of furnace was only necessary until such time as the combustion of the gas should be complete.

Mr. SIEMENS said that the combustion of the flame should be completed within the heating chamber of the furnace; the resulting hot gases should then be passed into the regenerators where they would give up their remaining heat by contact. In the combustion chamber the flame worked by radiation only; by the heating chamber he meant the combustion chamber in the case of a furnace, and by the *flame-flue* is meant the combustion chamber of a boiler.

#### NOTES ON THE CHEMISTRY OF SOAP.

BY C. R. ALDER WRIGHT, D.S.C., F.R.S., LECTURER ON CHEMISTRY; AND C. THOMPSON, F.C.S., DEMONSTRATOR OF CHEMISTRY IN ST. MARY'S HOSPITAL MEDICAL SCHOOL.

It has long been known that when common salt is added to a hot aqueous solution of potassium stearate or oleate, or of both salts mixed, together with larger or smaller quantities of analogous potash salts (such as the products of saponification of tallow, etc.), double decomposition takes place, resulting in the formation of potassium chloride and the soda soap corresponding with the potash soap originally employed; and further, that when neutral potassium or sodium stearate is treated with large masses of water it is partially broken up or *hydrolysed*, forming caustic alkali and an acid stearate, a similar behaviour being also noticeable in the case of analogous salts or soaps containing other fatty acids—e.g., palmitic. We have recently had occasion to study somewhat in detail these and other allied phenomena, and have

obtained results some of which it may be of interest to put upon record.

#### I.—On the Relative Affinities shown by Alkalis for certain Inorganic and Organic Acids in presence of each other.

The reaction of sodium chloride upon potassium stearate (or other analogous salt) above referred to has long been utilised for the purpose of obtaining hard soda soaps from soft potash soaps, in localities where the relative cost of potash and soda as saponifying agents has made it more convenient to employ the former alkali to react on the fatty matters used. It is usually regarded as an example of a general rule obtaining in such cases, and also employed in the calculation of analyses of mixed saline matters (such as the salts dissolved in a mineral water), which rule may be thus stated: When no interfering causes (such as relative insolubility) are at work, the stronger alkali is associated with the stronger acid, the order of alkaline strength being (1) potash, (2) soda, (3) ammonia. In the case of common salt and a potash soap, the stronger acid hydrochloric acid (which may be regarded as contained in the salt solution) in accordance with this rule tends to associate itself with the stronger base potash, whilst the weaker alkali soda combines with the feebler fatty acids of the soap. Similarly when nitrate of soda and carbonate of potash are brought together, nitrate of potash and carbonate of soda result, the stronger acid nitric acid combining by preference with the potash; this reaction has long been utilised as a means of producing salt-petre from nitrate of soda. The result of our experiments, however, is to show that this rule does not express the whole truth quite correctly. We find that when two alkalis and two acids are simultaneously present, there is a partitioning of each pair, giving rise to four distinct salts, the relative quantities of which depend to some extent upon extraneous circumstances, and are largely influenced by the relative masses of the two alkalis on the one hand, and of the two acids on the other. In certain cases, when potash and soda are the alkalis, the salts formed by the combination of potash with the stronger acid and soda with the weaker one, very greatly exceed in amount the other two salts formed by the combination of potash with the weaker acid and of soda with the stronger one; but by varying the conditions, and more especially the relative masses, these relationships may be greatly modified, and even inverted. For instance, sodium chloride and potassium stearate, when intermixed in such proportions relatively to the water present that the soaps formed are thrown wholly out of solution in the brine, will give rise to a mixture of potassium and sodium stearates as insoluble curd and of potassium and sodium chlorides in the brine, of which salts the second and third contain respectively the majority of the stearic acid and of the potash. But, on the other hand, if potassium chloride and sodium stearate be similarly intermixed in unsuitable proportions, the soap thrown out of solution will contain the majority of the stearic acid combined with potash instead of soda, and the majority of the soda will be found as chloride in the aqueous brine instead of in the soap, the action indicated by the rule of "stronger acid and stronger base" being thus apparently inverted.\*

\* In connection with the proportions in which the acids and bases of the two admixed salts will partition themselves so as to form four salts, it may be noticed that the reaction of potassium carbonate upon sodium nitrate really gives rise to four salts, and not to two only, the nitric and carbonic acids being both divided between the potash and soda respectively. That this is so is evident from the circumstance that if sodium nitrate and potassium carbonate in equivalent proportions be mixed, dissolved in water and

In the same kind of way, if caustic potash and caustic soda be mixed and brought into contact with a fatty acid, the latter being in quantity insufficient to neutralise the total alkali present, the rule of "stronger base and stronger acid" would suggest that potash soap would be formed to the exclusion of soda soap, were enough potash present to saturate the fatty acid. In point of fact, however, the product of the action is a mixture of potash and soda soaps, with excess of caustic potash mixed with caustic soda, where the ratio between potash and soda in the combined condition is sensibly the same as that of the uncombined alkalis, and consequently the same as that of the alkalis originally employed; so that in such a case the affinities of the two alkalis are sensibly equal. It is remarkable that practically the same result is obtained with most of the ordinarily occurring fatty acids, the nature of the acid not materially influencing the result. Thus the following numbers were obtained in a series of experiments with pure stearic acid; pure oleic acid; a mixture of stearic and oleic acids, etc., obtained by decomposing a tallow soap with hydrochloric acid; a similar mixture of nearly equal amounts of stearic, palmitic, and oleic acids, obtained from a palm-oil tallow soap; and the crude lauric acid (mixed with lower and higher homologues) similarly obtained from a cocoa-nut oil soap. In each instance the quantities of materials used were, for a given amount of fatty acids, exactly the neutralising amount of caustic potash together with the equivalent amount of caustic soda, so that two equivalents of total alkali were present to one of fatty acid. The alkaline leys being weighed out, the weighed quantities of fatty acids were added, and the whole heated to near 100° in a water bath, without stirring, until the fatty acids were melted, forming a supernatant layer. The whole was then briskly agitated for some time, and finally left at rest (after concentration by boiling down in the case of the cocoa-nut acids), the amount of water present being such that the resulting soaps were wholly insoluble in the alkaline ley; it sufficed to draw off and analyse a portion of the fluid, to obtain the data for calculating what fractions of the alkalis used were respectively converted into soap and left uncombined.

as is equivalent to the soda present, or if a potash soap be similarly treated with the equivalent quantity of caustic soda, the final product should be the same in each case—viz., a soap containing half the fatty acids combined with one alkali and half with the other, and an alkaline ley containing equivalent amounts of potash and soda. In point of fact, a close approximation to this result is actually attained in practice. Owing to the mechanical difficulty of obtaining thorough incorporation in experiments with small quantities made in the laboratory, the amounts of potash displaced by soda, or *vice versa*, usually fell a little below 50 per cent, but approached sufficiently near to that figure to indicate that it would have been arrived at with more complete means of admixture. Thus the following numbers were obtained with the tallow-soap acids above referred to, (a) when exactly neutralised with potash, and then stirred well with the equivalent amount of caustic soda solution; (b) when exactly neutralised with soda and then stirred with the equivalent amount of caustic potash solution—

(a) Percentage of Potash Soap converted into Soda Soap	(b) Percentage of Soda Soap converted into Potash Soap
48.8	46.0

Similar results were obtained with other fatty acids.

Most remarkably-different results were obtained in a parallel series of observations in which the carbonates of potash and soda were used instead of the hydroxides respectively. In these experiments various fatty acids were exactly neutralised either by caustic potash or soda, as the case might be, and were then well intermixed with aqueous solutions of the carbonate of the other alkali. Finally the mass was dried on the water-bath and treated with strong (nearly anhydrous) alcohol, which dissolved out the soaps and left behind the alkaline carbonates, the reaction invariably giving rise to four products—viz., potash soap, soda soap, potassium carbonate, and sodium carbonate, but in relative proportions widely differing from those observed with the hydroxides—the amount of potash contained in the mass as soap being to the soda similarly contained in far greater proportion than that of the total masses of potash and soda present as carbonates; in fact, when quantities of potassium carbonate were intermixed

Crude Lauric Acid (cocoa-nut oil).....	49.7	50.3
Mean ..	50.3	49.7

These figures clearly show that for all practical purposes the potash and soda existed in every case half as soap and half as uncombined hydroxide in the mixed mass resulting from the mechanical incorporation of molten fatty acid and two equivalents of caustic alkali, half as potash and half as soda.

It should hence result that if a soda soap be fused and then well intermixed with as much caustic potash

evaporated to dryness, the solid residue is always hygroscopic, or even deliquescent, indicating the presence of more or less unchanged potassium carbonate. Similar results are observed with chlorite instead of nitrate.

with soda soaps in proportions not exceeding the amounts equivalent to the soda in the soaps, by far the majority of the potash passed into combination with the fatty acids, equivalent quantities of sodium carbonate being formed; whilst on intermixing sodium carbonate with potash soaps, even in quantities largely in excess of the amounts equivalent to the potash present, only a comparatively small percentage of fatty acids became combined with the soda, forming an equivalent amount of potassium carbonate. Thus the following table exhibits side by side some of the numbers obtained, (a) on intermixing

soda soaps with carbonate of potash, (b) on intermixing potash soaps made from the same fatty acids with carbonate of soda. The fatty acids employed were the same mixtures of stearic and oleic, of stearic palmitic and oleic, and of lauric and homologous acids described above, together with the crude ricinoleic acid obtained by saponifying refined castor oil with caustic soda and decomposing with an acid—

proportions. A known quantity of fatty acids was divided into halves, and each half converted into neutral soap by addition of caustic potash to the one and caustic soda to the other. The two soaps were then mixed and dissolved in hot water (150 molecules  $H_2O$  to 1 molecule of mixed soap—i.e., to  $\frac{1}{2}$  molecule of potash soap +  $\frac{1}{2}$  molecule soda soap), and treated at a temperature not far from  $100^\circ C$ . with a

These observations throw some light on the effect well known to be produced on the texture and grain of certain kinds of soda soaps when melted and stirred with pearlash solution. The hard soda soap is partially converted into soft potash soap, thus modifying the texture, whilst the carbonate of soda formed as complementary product exerts a "closing up" or hardening action on the mass, avoiding the pastiness and softness that might possibly be caused by the presence of the potash soap when produced in any quantity. It is, however, to be remarked that inasmuch as no neutralisation of the extra alkaline matter thus added takes place, soaps thus subjected to "pearlashing" must necessarily contain "free alkali" to an extent proportionate to the amount of pearlash added, and hence may readily be rendered most objectionably alkaline and deleterious to sensitive skins when this process is adopted. Quantities of free alkali, equivalent to 10 or 12 per cent. of that present combined as soap, are not infrequently met with in "pearlashed" soaps, an amount entirely inconsistent with high quality from the point of view of suitability for application to tender skins.—*Vide* Section III.

It is thus evident that when fatty acids and carbonic acid on the one hand, and potash and soda on the other, are simultaneously present, the prevailing tendency is towards the formation of potash soap and carbonate of soda. Quite the opposite result is brought about if chlorides be substituted for carbonates, the prevailing tendency now being towards the formation of soda soap and potassium chloride; at least these salts are formed in preference to potash soap and sodium chloride when the relative masses of the two alkalis are nearly equal, although by modifying the relative masses the latter pair of salts can be made to be generated in preference to the former pair. Thus the following figures were obtained in a series of experiments carried out in such a way that the total potassium and sodium present were in equivalent

mixture of equivalent weights of potassium and sodium chlorides (20 molecules mixed chlorides, or  $10KCl + 10NaCl$ ) in the state of powder, poured in with continuous agitation kept up for some minutes. The curds that separated were collected after complete cooling (the proportion of water and saline matter being such that no soap then remained dissolved) and well pressed in calico, and finally were dried in the water-bath and boiled with strong alcohol. Small quantities of chlorides were thus taken into solution as well as the soaps, but as the chlorine thus present only represented an amount of alkali equivalent to from 2 to 5 per cent. of that equivalent to the fatty acid dissolved as soap, the error thus introduced was not sufficiently great to affect the general result, which was uniformly this, that between 1½ and 6 molecules of soda soap were contained in the alcoholic solution for 1 of potash soap. Thus with various of the fatty acids and admixtures thereof above described the figures given in the first table on page 628 were obtained, exhibiting considerable variation with the nature of the fatty acid, but always such as to indicate formation of soda soap to a notably greater extent than of potash soap.

In other series of experiments the quantity of sodium present was increased relatively to the potassium, under which circumstances, as might be expected, still larger proportions of soda soap were formed. On the other hand, increasing the amount of potassium present relatively to the sodium, decreased the amount of soda soap and increased that of potash soap until the latter predominated. Thus the figures given in the second table on page 628 were obtained in some experiments in which (a) potash soaps dissolved in M molecules of water were salted out by adding N molecules of sodium chloride for 1 molecule of soap; (b) soda soaps dissolved in M molecules of water were salted out by adding N molecules of potassium chloride for 1 molecule of soap.

It is thus evident that in the (*b*) series of experiments the soap thrown out of solution was essentially potash soap\*—a conclusion borne out by its consistency. It is noticeable, on comparing the figures in the (*a*) and (*b*) columns for each kind of fatty acid, that the tendency to convert potash soap into potassium

the one and the equivalent quantity of sodium chloride in the other, a perceptibly larger proportion of fatty acids becomes converted into soda soap than does into potash soap, indicating a greater tendency for potash to remain as chloride than for soda. Thus the numbers given on page 629 were obtained in four

chloride and soda soap by the action of sodium chloride, is *ceteris paribus*, distinctly more marked than the tendency to convert soda soap into sodium chloride and potash soap by the action of potassium chloride, precisely as might be inferred from the above experiments with equal molecules of potash and soda compounds.

A number of experiments were also made on the mutual reactions of ammonium chloride upon potash and soda soaps, and of potassium and sodium chlorides upon ammonia soaps. In accordance with the rule of "stronger acid and stronger base," it might be anticipated that on adding ammonium chloride to a potash or soda soap the chlorine will combine with the fixed alkali metal, an ammonia soap being the

series of observations, the numbers in the four last columns respectively indicating the percentages of total fatty acids employed as soaps converted—

- From the condition of ammonia soap to that of soda soap by salting out with sodium chloride;
- From the condition of ammonia soap to that of potash soap by salting out with potassium chloride;
- From the condition of soda soap to that of ammonia soap by salting out with ammonium chloride;
- From the condition of potash soap to that of ammonia soap by salting out with ammonium chloride.

complementary product; the experiments just described, however, would suggest that under certain conditions this action might be inverted, so that on adding potassium or sodium chloride to an ammonia soap more or less potash or soda soap might be formed, together with the equivalent amount of ammonium chloride. In point of fact this is the case; whilst almost complete displacement of fixed alkali from combination with fatty acid ensues when a potash or soda soap is dissolved in 200 molecules of water, and after cooling well stirred with twenty molecules of ammonium chloride; the opposite effect is produced when twenty molecules of potassium (or sodium) chloride is similarly stirred into a cold solution of an ammonia soap in 200 molecules of water, the majority of the fatty acids becoming transformed into potash (or soda) soap, and a corresponding amount of ammonium chloride being formed. It is remarkable in this connection, moreover, that in two experiments, alike in all respects save that potassium chloride is used in

The ammonia soaps used for series (*a*) and (*b*) were prepared by just fusing the fatty acids and then well incorporating moderately concentrated ammonia solution in quantity slightly in excess of the amount equivalent to the fatty acids, and finally dissolving in water so as to obtain nearly clear solutions; those obtained in series (*c*) and (*d*) invariably decomposed spontaneously during preparation, giving off more or less free ammonia and forming acid ammonia soaps.

On the whole, all the experiments tend to show that when a soap and a neutral salt containing an alkali different from that in the soap are brought together, four salts are formed in relative proportions, largely governed by the relative masses of the two alkalis and the two acids; but there is always a more or less marked tendency for the stronger base and stronger acid to associate themselves together in proportions greater than those deducible from their actual masses relatively to the weaker base and weaker acid. When the salt is carbonate, since carbonic acid is a weaker acid than the fatty acids of soap, the prevailing tendency is (when the alkalis are potash and soda) to form potash soap and sodium carbonate; and when the salt is chloride,

\* This conversion of soda soap into potash soap by salting out with potassium chloride does not appear to have been hitherto noticed; at least we have been unable to find any printed record of the observation amongst the voluminous literature relating to soap that has come under our inspection.

since hydrochloric acid is a stronger acid than the fatty acids of soap, the prevailing tendency is to form potassium chloride and soda soap. But these ten-

results were obtained in various analogous experiments with mixtures of acids. On the whole, it appears that the diacid ammonia salts of the satu-

Crude Ricinoleic acid (castor-oil)	66.0	—	99.7	99.5

It is noticeable, on comparing the figures in the (a) and (b) columns, that the tendency of soda to pass from the state of chloride to that of soap is, *ceteris paribus*, more strongly marked than the similar tendency in the case of potash, precisely as might be anticipated from the previous results.

\* The potash soaps of cocoa-nut and castor-oils formed could not be separated from the brines so as to permit of analysis.

dencies can be very largely overcome by the action of mass, especially with chlorides.

On the other hand, when only fatty acids are present, and no mineral acid or carbonate, there does not appear to be any marked tendency for either potash or soda to combine with the acid by preference.

In connection with the spontaneous decomposition of ammonia soaps, the following observations may be of interest:—A number of ammonia soaps was prepared by thoroughly intermixing fatty acids just fused with excess of moderately strong ammonia water, the whole being then dried over sulphuric acid for some months; the mass was pulverised and stirred up occasionally when sufficiently dry, samples being drawn from time to time and submitted to analysis. In all instances it was found that a rapid loss of ammonia took place during the first few weeks, until the composition approached that of a diacid salt, NH<sub>3</sub>.2HX (where HX represents the acid), after which the rate of loss became much slower. The temperature during the period of standing over sulphuric acid was rarely as high as 18° C., the substances being kept in an unwarmed room during winter and spring; on further heating the partly-decomposed salts to temperatures not very elevated, a distinct evolution of ammonia took place; whilst after heating for a few hours to 100° C., practically all was expelled and nothing but fatty acids left. The above figures represent the progressive loss of ammonia observed with crude lauric acid (from cocoa-nut oil), pure stearic acid, crude ricinoleic acid (from castor-oil), and nearly pure oleic acid, when converted into ammonia salt containing a small excess of ammonia intermixed therewith; similar

rated fatty acids (lauric and stearic) lose ammonia distinctly more slowly than the corresponding salts of the unsaturated acids (oleic and ricinoleic).

## II.—On the Amounts of Hydrolysis effected in Soaps with varying proportions of Water.

The decomposition of neutral soaps by water into acid soaps and free alkali has long been known as a fact, but systematic measurements of the amount of decomposition effected under varying conditions with different kinds of soaps do not as yet appear to have been made. Having recently had occasion to study this point somewhat minutely, we have arrived at a number of figures capable of being expressed graphically as curves, and leading to the following general conclusions:—

(1.) The amount of hydrolysis brought about by the action of a given quantity of water on a neutral soap is variable with the nature of the fatty acid from which the soap is made, but in all cases increases with the amount of water employed relatively to the soap, but less rapidly; so that curves plotted with the amounts of water as abscissæ and the proportions of alkali set free as ordinates are concave downwards.

(2.) Addition of excess of alkali to a neutral soap causes a diminution in the amount of hydrolysis effected under given conditions, to such an extent as completely to stop the action with comparatively small proportions of water when the free alkali only amounts to a fraction—say 20–25 per cent.—of the alkali combined with the fatty acids.

(3.) Alcohol, even when not absolutely anhydrous (90–95 per cent.), does not decompose ordinary neutral soaps into free alkali and acid salts; if, however, water be added to an alcoholic soap solution, more or less hydrolysis is brought about; so that if a gelatinous mass of neutral soap dissolved in strong spirit (containing a little phenol phtalcin) be treated with water, a more or less strongly-marked colouration is noticeable as the water diffuses into the mass. (This affords a good lecture illustration.)

The experiments were made as follows:—The soaps examined were either prepared by ourselves or obtained from manufacturers with information as to the fatty acids present; they were carefully analysed, and in those cases where minute amounts of free alkali were present corrections were made for these

small amounts.\* Weighed quantities of soap representing known amounts of *anhydrous* soap were dissolved in known quantities of distilled water on the water-bath, and after cooling to near the ordinary temperature the liquids were treated with pure sodium chloride, so as to throw out of solution all, or nearly all, the soap as a curd. The curds thus precipitated, on drying and dissolving in alcohol, were always more or less acid, phenol phthalein being the indicator; so that one way of determining the amount of hydrolysis was to determine the quantity of alcoholic potash or soda solution requisite to neutralise this acidity. It was found, however, in practice to be far more convenient to determine the alkali contained in an aliquot portion of the brine, correcting the amount found for the free alkali originally contained in the soap (when any). With smaller proportions of water the addition of moderate quantities of salt sufficed to throw all soap out of solution so perfectly, that at most only traces of fatty acids could be obtained from the brine by acidulating and shaking with ether; with larger proportions it was found convenient to evaporate the brine until nearly saturated, and filter again from any soap thrown out of solution during the evaporation, using only a fraction of the salt requisite to saturate the water for the salting out, rather than to use more salt in the first instance and titrate without evaporation, greater accuracy in hitting the terminal reaction being thus attained. With cocoa-nut oil soap the brines were evaporated to dryness, and then treated with just sufficient water to dissolve the salt and filtered; in this way liquids free from more than traces of soap were obtained, the soap originally contained in the brine before evaporation being thus eliminated.

The following corrected mean values were obtained in a lengthy series of experiments with various soda soaps, all of which were either neutral or only faintly alkaline; the numbers represent the quantities of  $\text{Na}_2\text{O}$  set free by hydrolysis, reckoned per 100 parts of  $\text{Na}_2\text{O}$  contained in the soap combined with fatty acids,  $x$  molecules of water being used for one of anhydrous soap.

of these three homologous acids, that for the acid of highest molecular weight underlying, and that for the acid of lowest molecular weight overlying, the third. It cannot, however, be hence inferred that the soda salts of acids of the fatty series are decomposed by water with the greater ease the lower their molecular weight, for Julius Thomsen's thermo-chemical investigations (*Thermochemische Untersuchungen*, i. p. 372) show that sodium acetate is not measurably broken up by water.

The curve for tallow-resin soap (primrose) indicates that the presence of a certain amount of resin soap in a mixture mainly consisting of sodium stearate and oleate does not materially affect the rate of hydrolysis, since the curve for this soap lies between the stearic and oleic acid curves.

The annexed diagram represents these values graphically, the value of  $X$  being abscissæ and the others ordinates.

It is noticeable, in connection with these figures, that the curves for stearic, palmitic, and lauric acids (cocoa-nut oil) lie in the order of the molecular weights

\* For the determination of the free alkali the soap was dried and boiled with strong alcohol, and filtered hot; the filtrates were always neutral, showing absence of caustic alkali; the trifling residue of carbonate sometimes left on the filter was treated with standard acid in the usual way. *Vide infra*, Section III.

The curves obtained with oleic acid and cotton-seed oil (which appears to contain some amount of an acid analogous to the linoleic acid of linseed-oil) overlie all the others, cocoa-nut oil excepted; ricinoleic acid, however, furnished a soap that hydrolysed markedly less readily than sodium oleate, though more readily than sodium palmitate and stearate.

The following numbers, obtained with some of the above soaps, illustrate the effect of the presence of free sodium hydroxide in diminishing the amount of hydrolysis produced by given quantities of water,

the values being in all cases notably below those obtained as above with neutral soap solutions:—

On testing absolutely-neutral soaps in this way, numbers were obtained sometimes indicating a small

NATURE OF FATTY ACIDS USED.	Extra Na <sub>2</sub> O added to Solution, per 100 combined as Soap.	Hydrolysis brought about by x Molecules of Water.		
		x=150	x=250	x=2000
Crude Lauric Acid (cocoa-nut)	11.0	1.1	1.6	2.0
Cotton-seed Oil Soap .....	15.0	nil.	nil.	6.5
Stearic and Oleic (tallow) ....	20.0	nil.	nil.	nil.
Tallow Resin (primrose) .....	15.0	nil.	0.1	1.3

Similar results were obtained in numerous other experiments of the same kind.

### III.—Comparative Results yielded by Different Processes in ordinary use for the Determination of "Free Alkali" in Soap.

In connection with this subject the following notes may be of some interest, being obtained as the result of a large number of comparative analyses made for the express purpose of testing the accuracy of the various methods. Three methods were examined, which for convenience of reference may be designated respectively as the "Alcohol test," the "Fatty Acid titration test," and the "Salting-out test" (or A.T., F.A.T.T., and S.O.T.). The first consists of the following operations:—The soap is dried, and then boiled with a sufficient amount of strong alcohol—or, better, absolute alcohol. The filtrate and washings are then titrated with alcoholic acid or alkali, using phenol phthalein as indicator, so as to obtain the positive or negative alkalinity of the solution (negative alkalinity indicating free fatty acid or diacid salt). The residue on the filter, consisting of carbonates, etc., is then titrated as usual, and the total alkalinity taken as the algebraic sum of the two valuations.\* A number of direct experiments showed that if a perfectly-neutral soap were taken to start with, dissolved in alcohol, and added to a known quantity of alcoholic potassium or sodium hydroxide, the amount of alkali present was still correctly determinable with phenol phthalein as indicator, the presence of the soap introducing no marked error; whilst, on the other hand, if the same soap were dissolved in water and a known amount of sodium carbonate added, this amount was always sensibly indicated by the alkalinity of the residue obtained by evaporating to dryness, treating with alcohol, and filtering and washing thoroughly; whence it may be inferred that the A.T., when properly applied to a soap, gives accurate information, not only as to the total "free alkali," but also as to the proportion thereof existing as hydroxide and carbonate respectively. Accordingly, this process may fairly be taken as a standard of comparison for the others.

The second process (F.A.T.T.) consists in determining the total alkali present (that existing as soap together with the free alkali), separating the fatty acids in any convenient way, and finally dissolving these in alcohol and titrating with alcoholic potash or soda with phenolphthalein (or other suitable colouring matter) as indicator. Although at first sight this process would seem likely to be exact, yet in our hands it seemed almost invariably to be affected by a sensible error of uncertain direction.

\* It is not impossible for a free fatty acid (or, rather, a certain proportion of diacid salt) to coexist side by side with an alkaline carbonate in a solid soap; for example, in a soap prepared by intermixing a free fatty acid with a strong alkaline solution.

positive excess of alkali, and sometimes a small negative one (excess of fatty acids); and in the same way, soaps that contained small or moderate amounts of free alkali when tested by A.T. often yielded distinctly different results when tested by F.A.T.T., the difference being sometimes + and sometimes -. As range of variation, from + 3 per cent. of the alkali present as soap to - 3 per cent. of the same usually represented the extremes; but occasionally still larger discrepancies were observed, whilst concordance within  $\pm 1$  per cent. by the two tests was the exception rather than the rule. That no particular systematic error in one direction obtained was evidenced by the fact that taking the average of a long series of duplicate tests with different soaps, the + differences and the - differences sensibly balanced one another. Thus the following figures may be quoted as illustrations, the numbers representing the amounts of free alkali found per 100 combined as actual soap—i.e., if the total alkali were 85 per cent. of the soap itself, and the free alkali were 1.0 per cent., then the free alkali would be  $\frac{1.0}{85-1.0} = \frac{1.0}{7.5} = 13.3$  per cent. of the combined, and so on.

NATURE OF SOAP.	A.T.	F.A.T.T.	Excess of A.T. over F.A.T.T.
Cotton-seed Oil Soap .....	7.0	14.0	-7.0
Chiefly from Bleached Palm Oil	5.0	10.8	-5.8
Primrose .....	1.1	5.0	-3.9
Transparent Soap, made by Spirit Process, containing 10 per cent. of Sugar .....	0	2.0	-2.0
A Curd Soap (highly alkaline)	18.3	18.1	+0.2
A British Cold Process Soap..	7.4	8.8	-1.4
A Continental Toilet Soap ...	1.2	-4.1	+5.3
A British ditto ....	8.0	2.5	+5.5

The four extreme differences here tabulated (first and last pairs of samples) were unusually large, the differences ordinarily not exceeding  $\pm 3.0$ .

Inasmuch as an uncertainty in the actual amount of free alkali present thus seems to exist when the F.A.T.T. is used, amounting to  $\pm$  some per cents. of the alkali present as soap, it follows that the F.A.T.T., though convenient and useful in the examinations of various kinds of soap where a sharply exact estimation of the free alkali is not material, cannot be safely used for the purpose of deciding whether the amount of free alkali in, for example, a toilet soap falls beyond a small limiting quantity. Thus in following the classification suggested by one of us in the Cantor Lectures on Toilet Soap, delivered some months ago before the Society

of Arts,\* the F.A.T.T. is practically useless, inasmuch as it is not possible to affirm certainly by its means whether or not a given sample of soap contains less alkali in a free state than  $\frac{1}{10}$ th part (2.5 per cent.) of that present as soap. The test might indicate perfect neutrality when upwards of 2.5 per cent. of free alkali is present; or it might condemn a soap as passing beyond the limit of 2.5 per cent. when really the soap might be perfectly neutral. On the other hand, for the commercial valuation of the detergent power of strongly alkalis or silicated soaps where a large portion, or even the majority, of the alkali present is not combined with fatty acids, the F.A.T.T. is often extremely convenient, necessitating but little additional trouble after the fatty acids formed on decomposing with acid have been determined.

The third process (S.O.T.) is usually carried out in much the same way as the experiments above described on Hydrolysis, and consequently is apt to be even more inexact than the F.A.T.T. A certain amount of liability to error could no doubt be avoided by uniformity in procedure—*e.g.*, by always taking such a quantity of water to dissolve the soap in as would represent approximately a constant number of molecules of water to one of soap; but even if sources of error through varying proportions between water and dry soap could be avoided, there would remain the objection that a widely varying excess of alkali is always present in the brine over and above that to be determined, owing to the hydrolytic action of the water; and it is impossible to apply any mean correction sufficiently accurate for use to obtain exact results, because not only is the hydrolysis due to a given amount of water variable with the nature of the fatty acids present, but also it varies for a given fatty acid with the amount of free alkali in the original soap, increase in alkalinity of soap diminishing amount of hydrolysis. The figures on next column may be quoted as illustrations, being some obtained in one series of comparative valuations in which for one molecule of dry soap approximately 150 molecules of water were constantly used (roughly speaking, about ten parts by weight of water to one of dry soap); the soap being dissolved by the aid of heat, the solution was cooled and treated with an amount of pure common salt equal to one-fifth the weight of water, the curdy mass being then filter-pumped, and the last portions of adherent alkaline brine washed out with a few ccs. of saturated salt solution. With soaps largely consisting of cocoa-nut oil salts, an additional error is apt to be occasioned by incomplete precipitation from solution of soap by salt, apart from the increased error due to larger relative hydrolytic action on this class of soaps.

Considerably larger discrepancies between the results of the two methods were observed when relatively larger quantities of water were employed, as, for example, when a solution of soap (two, five, or ten per cent.) was precipitated by adding to it twice its volume of saturated brine, a mode of workings sometimes adopted by soap analysts. It is hence evident that whilst the S.O.T. is often very convenient for testing highly-alkaline soaps commercially (the hydrolytic action of water on such soaps being a minimum), it is not of much value for discriminating the small amounts of

free alkali which at most are permissible in high-class toilet soaps, inasmuch as the probable error of a test by this method will often (as with the F.A.T.T.) exceed the maximum amount of free alkali compatible with classification as a first-rate article; whence, finally it results that the "alcohol test" is the only one of real utility in such cases; independently of which, as above stated, it gives information as to the causticity or otherwise of the free alkali in a way impossible with the other two tests.

NATURE OF SOAP USED.	A.T.	S.O.T.	Excess of S.O.T. over A.T.
Pure Cocoa-nut Oil Soap, not strongly alkaline .....	5.0	9.1	4.1
Another sample of ditto .....	2.8	5.8	3.0
A British Toilet Soap, largely made from Cocoa-nut Oil .....	1.3	5.8	4.5
A foreign Toilet Soap, largely made from Cocoa-nut Oil (neutral) .....	0	3.5	3.5

A tolerably Alkaline Curd Soap .....	18.3	18.3	0
Pure Stearic Acid Soda Soap (neutral) .....	0	0.7	0.7

#### IV.—On two New Patents connected with Soap Manufacture.

In connection with the above-described results, it may be of interest to refer briefly to two recent improvements introduced by one of us. One of these is mechanical rather than chemical, being primarily intended to diminish the large amount of waste unavoidably caused in the ordinary process of cutting up and shaping large rectangular blocks of soap for the formation of tablets, owing to the production of scrap; this is effected by forcing the hot fluid soap (by means of a pump, hydraulic ram, screw, or other convenient means) through a system of cooling tubes so arranged that the soap issues therefrom as a series of streams of soap just upon the solidifying point, but sufficiently soft and plastic to weld together completely on further passing into a moulding tube, from which a bar issues at the far end of dimensions regulated by a movable mouth-piece—the various tubes being jacketted, and so maintained at the particular temperatures requisite for the particular kind of soap operated upon.† In this way a considerable saving of time, labour, working space and material is effected as compared with the ordinary system, inasmuch as a continuous production of bar goes on as long as the supply of molten soap lasts.

The other is a purely chemical process, devised for the purpose of getting rid of the *bête noire* of the toilet-soap maker—*viz.*, excess of alkali present in forms other than true soap, usually as carbonate or hydroxide. In the manufacture of Castile soap a small quantity of ferrous sulphate is often added to

\* *First Grade*.—Soaps which are, if not actually neutral, at any rate so far devoid of free alkali that the amount of total alkaline matter present in forms other than actual soap does not exceed  $\frac{1}{10}$ th part (2.5 per 100) of the alkali present combined with fatty acids as soap.

*Second Grade*.—Soaps in which the free alkali, although exceeding  $\frac{1}{10}$ th part (2.5 per 100) of that combined as soap, does not overpass  $\frac{1}{10}$ th of that amount (7.5 per 100).

*Third Grade*.—Soaps in which the free alkali exceeds  $\frac{1}{10}$ th (7.5 per 100) of the alkali combined as true soap.

Journal Soc. Arts, xxxiii. 1121, Nov. 6, 1885.

† *Vide* Patent Specification No. 10,601, 1884.

the mass before cooling, for the purpose of producing the peculiar "mottle" of this class of soap;\* the sulphuric acid of this salt converts a portion of the free alkali into sulphate, thereby diminishing the free alkalinity. It is obvious that this latter result would be equally brought about by using any other salt that would act on the alkali of the soap in the same way as ferrous sulphate; but inasmuch as a metallic oxide would also result, the use of such compounds is objectionable, because staining and discolouration of the mass would be apt to be brought about, as well as other inconveniences, owing to the presence of metallic compounds. By substituting an ammoniacal salt this difficulty is obviated; the free alkali becomes a neutral salt corresponding with the ammoniacal compound employed, whilst the complementary product is ammonia (free, or as carbonate, in either case readily volatile) which escapes, part immediately, the remainder during the processes of cutting up and shaping, stamping, and exposure to air to dry and harden before boxing; even should a minute amount of ammonia be retained in the centre of the tablet, this is of no practical consequence, as the action of ammonia on the skin (as on woollen goods generally) is well known to be far less corrosive and injurious than that of an equivalent amount of fixed alkali, especially soda. This method of getting rid of free alkali is particularly applicable to "milled" soaps, inasmuch as the exposure to air in the form of thin ribbons, which necessarily takes place over and over again during the grinding together of the stock soaps and colouring matters, etc., ensures the complete volatilisation of the ammonia; so that only the faintest traces, or none at all, can be found in the finished tablets.

A working model of the machine described, and specimen bars made thereby (natural size), were exhibited; as also specimens of remelted and milled toilet soaps de-alkalised by the ammonia process, which was also illustrated in operation on the small scale.

#### DISCUSSION.

The CHAIRMAN, in opening the discussion, said the authors had referred to "mass action" as applied to the chemistry of soap; in his opinion many other departments of industrial chemistry involved this principle as well.

Mr. LANT CARPENTER had been much struck by the authors' views upon "mass action." It might account to some extent for the differences observed by wool-sourers and other large users, in the behaviour of batches of soap precisely similar in composition so far as chemical analysis went.

Mr. SAMUEL HALL thought that more stress was often laid on the necessity for having no excess of alkali in soap than the question demanded.

Mr. MACTEAR could fully corroborate Mr. Lant Carpenter's remarks. He had found much difficulty in producing batches of soap of uniform strength, to suit makers of fine Scotch tweeds. Sometimes a soap completely destroyed the colour, though differing in constitution in no degree from a previous batch deemed quite satisfactory. He thought that the author's proposal to replace the free alkali by ammonia as likely to aid in securing uniformity in this direction. About ten years ago an apparatus for squirting soap had been brought before him by an American. But it differed in this respect from that exhibited—viz., in squirting the soap into a single

large tube instead of into several small ones. The result was that it was almost impossible to cool the soap unless a very long tube was employed, or the action was stopped every now and then. The apparatus before the meeting seemed to have effectually surmounted this difficulty.

Dr. ALDER WRIGHT, in reply, said that he believed it was the practice for certain firms to remelt their soap with some palm oil or other easily saponifiable fat, in order to neutralise any excess of alkali. Many other methods for removing excess of alkali from soap had been proposed at various times, but all had more or less failed in certain cases. What Mr. Mactear had said in reference to the American squirting machine was quite new to him; he had been under the impression that his machine was the first of the kind. In reply to Mr. Hall, it is not the dissolving of soap in water which causes excess of alkali to be objectionable, but the rubbing of this irritant on the skin. It had been over and over again established that if more than two or three per cent. of the total alkali were present in the form of carbonate, this would be enough, if used day after day, to produce most uncomfortable irritation, especially on the tender skins of ladies and children.

### THE LIME PROCESS FOR THE PURIFICATION OF COAL GAS.

BY V. H. VELEY, M.A., F.I.C.,

*Of the Chemical Laboratory, Christ Church, Oxford.*

#### PART I.

THE impurities in coal gas, after passage through the scrubbers, containing sulphur as a constituent, are of three distinct kinds: (1.) Hydrogen sulphide. (2.) Substances yielding hydrogen sulphide when passed over heated surfaces, especially finely-divided platinum. These consist principally of carbon disulphide and traces of hydrogen thiocyanate, and probably carbon oxysulphide; the presence of the first having been further demonstrated by the production of its compound with triethyl phosphine (Hofmann), and its extraction from lime purifiers (Leicester Greville). (3.) Substances not convertible into hydrogen sulphide under these conditions, but burnt into sulphurous and thence to sulphuric acid, as estimated by the Metropolitan Gas Referees' sulphur test. These two latter kinds are generally classified as "sulphur compounds." The recent researches of Victor Meyer and his pupils on thiophen ( $C_4H_4S$ ), which was first isolated from coal-tar benzene, and the relationship between this substance and pyrroline, seem to indicate that it, or its homologues, are amongst the sulphur compounds of the third class. The writer is now investigating this point. The principal purifying agents, adopted for the removal of members of the first two classes are ferric oxide and calcium hydrate, either in the damp state or in the form of milk of lime. The reactions taking place under various conditions between (1) calcium hydrate and hydrogen sulphide, (2) between calcium sulphide and carbon disulphide, under various conditions, and (3) the changes and decompositions induced by various substances likely to be present in coal gas issuing from the scrubbers, are the subjects of the present paper.

#### *Reaction between Calcium Oxide and Hydrate with Hydrogen Sulphide.*

The nature of the chemical changes between these substances has been the subject of investigation by

\* Many so-called mottled soaps of modern make are prepared in quite a different way; these substances differing from the old-fashioned mottles in being heavily watered, and consequently requiring a different mode of treatment to ensure the mottled appearance.

† *Vide* Patent Specification No. 14,681, 1881.

Berzelius\* and Rose;† but more recently by Divers and Shimidzu,‡ Folkard,§ W. Foster, and the writer.||

Firstly, it has been observed that, at temperatures below 100° C., perfectly-dry hydrogen sulphide is not absorbed by perfectly-dry calcium oxide†—a phenomenon perfectly analogous to the non-absorption of dry carbonic anhydride by dry calcium oxide. The explanation in both cases is probably similar. Thus, in the latter case a small proportion of the calcium oxide dissolves in the trace of water. The solution absorbs the carbonic anhydride to form calcium carbonate, which is precipitated, and thus removed from the sphere of action; leaving the water to take up another small quantity of calcium hydrate, and so *ad infinitum*. In the former case, the calcium hydrate is dissolved as calcium hydrosulphide,  $\text{Ca}(\text{SH})_2$ . This in its turn is decomposed into calcium hydroxy-hydrosulphide,  $\text{Ca}(\text{SH})(\text{OH})$ , which is precipitated; thus leaving the water to dissolve another portion of the calcium hydrate.

Secondly, if dry hydrogen sulphide is passed over calcium hydrate, calcium monosulphide and water are formed, in accordance with the equation—

a change effected readily and completely at temperatures ranging from 80° to 100° C., but more slowly at ordinary temperatures, owing to the formation of caked masses of the monosulphide, which enclose unaltered particles of the unchanged hydrate. As, however, there seems to be some doubt as to the completeness of the change at ordinary temperatures, the following experiment may be quoted on this point, with a sample of oxide, the preparation of which has been described at length in the author's paper in the *Journal of the Chemical Society*.

#### I.—Hydration of the Oxide.

3·0619grm. of calcium oxide gave 4·1142grm. of calcium hydrate.

Ratio of $\text{Ca}(\text{OH})_2$ to $\text{CaO}$	Found.	Theory.
..	1·323	1·321

#### II.—Synthesis of the Sulphide.—Temperature 15° C.

Condition of Experiment.	Weight of Calcium Compound. 4·000 Grammes.	Difference. Grammes.	Water Collected. Gramme.	Total Gain. Grammes.
After treatment with hydrogen sulphide for six hours, and hydrogen for two hours	5·5396	1·5396	0·0105	1·5301
" "	5·6328	0·1132	0·0151	1·6734
" "	5·6866	0·0228	0·0089	1·7311
" "	5·7011	0·0418	0·0212	1·7701
" "	5·7512	0·0398	0·0038	1·8136
" "	5·7474	0·0038	0·0010	1·8138
" "	5·7326	0·0148	0·0135	1·8131

At this point the experiment was stopped, as the substance seemed to be only dehydrating slowly, as shown by the loss in weight of lime compound being equal to the gain in weight of the drying tube.

The total gain required by theory for the reaction—

is 1·837 grammes, of which 1·8131 grammes were found, or 98·74 per cent.

#### III.—Analysis of the Resultant Substance.

Gramme.	Gramme.	Percentage.	Mean.
0·3854 gave 0·511 $\text{CaSO}_4$	.....	= 39·22Ca	39·22
0·2240 .. 0·153 $\text{BaSO}_4$	.....	= 27·75S	27·75
0·2008 .. 0·382 $\text{BaSO}_4 + 0·0038$	.....	= 27·75S	27·75
0·2106 .. 0·079 water	.....	= 32·03	32·03
0·1866 .. 0·061 .....	.....	= 32·91	32·18
			99·15
		Oxygen, by difference	00·85
			100·00

Atomic ratio of calcium to sulphur = 1·13:1.

Comparing, then, the results of the analysis and the synthesis, 0·85 per cent. of oxygen is equivalent to 3·9 per cent. of calcium hydrate. Therefore, of the 4 grammes of calcium hydrate taken, 3·844 grammes only entered into the reaction.

Grammes.	Grammes.	Grammes.
3·844 $\text{Ca}(\text{OH})_2$ should yield	3·753 $\text{CaS} +$	1·9021 $\text{H}_2\text{O}$
0·136 $\text{Ca}(\text{OH})_2$ are equal to	0·118 $\text{CaO} +$	0·038 $\text{H}_2\text{O}$

The 4·0 grammes of  $\text{Ca}(\text{OH})_2$  gave 3·844  $\text{CaS} + \text{CaO}$  1·9021  $\text{H}_2\text{O}$

The error in both cases is slightly more than 1 per cent., probably accounted for by the difficulty of rigidly excluding all traces of air throughout an experiment lasting many hours, and the inevitable formation of small quantities of calcium thiosulphate. However, both the synthetical and analytical results are sufficient to show that 96 to 98 per cent. of the calcium hydrate is converted into the sulphide at ordinary temperatures. In the course of experiment, it was observed that the above reaction could be more rapidly effected in the presence of water in excess of that required for the production of the hydroxide—a result to be explained by the solution of the larger quantity of the hydroxide, and the greater readiness with which the hydrosulphide is temporarily produced.

The sulphur compounds of calcium have often been described as being of a blue or bluish-green colour; but this tint, which gave rise to the technical term "blue billy," is due to impurities of ferric oxide contained in the native lime. Pure calcium monosulphide is perfectly white; but rapidly turns a pale yellow on exposure to air, owing to the formation of calcium thiosulphate. The green-blue tint of the crude foul lime can be successfully imitated by slaking the pure specimens of the oxide with a solution containing 1 part of iron in 500,000 parts of water, and passing hydrogen sulphide over the product.

Thirdly, if hydrogen sulphide is passed into water in which calcium oxide is suspended, calcium hydrosulphide is formed, in accordance with the equation—

This substance eventually crystallises out in white acicular needles. This change is the more perfect the lower the temperature at which it is effected; in fact, a freezing mixture is required for the crystallisation of the hydrosulphide. But, in any case, the hydrogen sulphide in excess of that required for the monosulphide is readily evolved by passing into the solution an inert gas, such as hydrogen or nitrogen, or even by mere exposure to the air.\*\* Under any of these conditions, the sparingly-soluble hydrated calcium sulphide or calcium hydroxy-hydrosulphide is precipitated in accordance with the reaction—

a change accompanied by the evolution of heat, for, according to Thomsen,†† the substitution of an atom of sulphur by an atom of oxygen in the case of compounds of alkalis and alkaline earths corresponds to a heat evolution of 51·3 heat units.

*Reaction between Calcium Sulphide or Hydrate and Carbon Disulphide.*

Nearly fifty years ago, Berzelius\* described the preparation of calcium sulphocarbonate or thiocarbonate by digesting together calcium sulphide, carbon disulphide, and water; but no analyses were given of the resultant substance. More recently D. Walkert prepared a basic calcium thiocarbonate—

by agitating milk of lime with carbon disulphide—a reaction effected, according to Sestini,† by exposure of such a mixture to sunlight. According to Sestini's description, it would appear highly probable that there can be formed a series of such combinations of the hydroxide and thiocarbonate, varying in colour from a pale yellow to a deep red, according to the proportion of carbon disulphide contained therein. Sestini, Ganvy, and Rotondi proposed to decompose such a liquid by potassium carbonate as a cheap method for the preparation of a solution of potassium thiocarbonate, an antidote to the *phyllorrea*; but, according to the experiments of Rotondi,‡ a solution of calcium thiocarbonate could not be obtained containing more than 5 per cent. combined carbon disulphide.

Now, it has been observed, both on the manufacturing and on the small scale, that perfectly-dry calcium sulphide does not absorb carbon disulphide. In the course of the writer's experiments, this point has been determined, first, by passing hydrogen, mixed with the vapour of carbon disulphide, over a weighed quantity of pure dry calcium sulphide; no gain in weight was observed, nor alteration in colour, nor diminution of proportion of carbon disulphide present in the gas as indicated by Mr. Vernon Harcourt's colour test. Secondly, some calcium hydrate was slaked, and moistened so as to form a material of consistency similar to that used in gas-works. Dry sulphuretted hydrogen then passed in to convert it into sulphide, and determinations were made of the amount of carbon disulphide absorbed (the relation between the volume of the gas and the volume of the purifying material being the same as that in practice) when dry hydrogen mixed with the vapour of carbon disulphide was passed into it. But this sulphide, instead of absorbing all the carbon disulphide present in the gas, absorbed only 60 per cent., and after a time became inactive; but its activity was restored, and increased to its full value, by merely damping it. This result, on the small scale, is precisely analogous to that obtained on the large scale when the lime purifiers are said to "work dry." On moistening the calcium sulphide with a large quantity of water, and passing carbon disulphide into it, it turns rapidly from a white to an orange yellow, and thence to a red colour; a red liquid ultimately draining down from the sulphide. On evaporation of the liquid, a basic calcium thiocarbonate— $\text{Ca}(\text{OH})_2\cdot\text{CaCS}_2\cdot 7\text{H}_2\text{O}$ —separates out. But the nature of the reaction between the calcium sulphides and carbon disulphide can best be studied by passing the vapour of the latter substance into a solution of calcium hydrosulphide. At first hydrogen sulphide is given off in large quantities, with precipitation of the calcium hydroxyhydrosulphide. When this is completed, the absorption of carbon disulphide commences, as evidenced by the liquid becoming nearly solid by the formation of yellow crystals of another basic calcium thiocarbonate—probably—

These in their turn dissolve, to form the above-mentioned red liquid. It results from these observations that neither dry calcium sulphide nor calcium hydrosulphide is an active material for removing carbon disulphide, but calcium hydroxy-hydrosulphide. The absorption of the carbon disulphide is dependent upon the solution in small quantities of the hydroxy-hydrosulphide, the combination of the dissolved portions with carbon disulphide to form a thiocarbonate—whose solubility increases with the proportion of carbon disulphide taken up. But whatever the method of conducting this change, the evolution of hydrogen sulphide is concomitant with the absorption of the carbon disulphide, and the reaction expressing these changes can be written probably thus—

This evolution of hydrogen sulphide was rendered evident, in the usual way, by lead acetate paper. These results are in perfect accordance with the experience of gas engineers, who have noticed that the material from the lime boxes worked according to Mr. H. E. Jones's process (described in his paper read before the Institution of Civil Engineers) differs entirely from ordinary spent foul lime in emitting a faint odour of carbon disulphide, but no quantity of hydrogen sulphide, and in being slowly oxidisable. The above experiments explain the reason of the inactivity of a lime purifier, when it has become "over-fouled," or fouled at a low temperature,\*\* for the active calcium hydroxy-hydrosulphide has become converted by the excess of hydrogen sulphide into the inactive hydrosulphide. To restore its activity, either air is blown into the purifiers, or the foul lime is taken out, broken up, and returned to the box; the exposure causing it to steam and emit a considerable quantity of hydrogen sulphide. The colour also changes from a white to a dark green; owing, in some way or another, to the conditions being favourable to the formation of the ferrous sulphide. In the former of these cases the blast of air removes the excess of hydrogen sulphide, and causes the production of the active hydroxy-hydrosulphide; while in the latter this change is effected both by the mechanical process of breaking up, and thus exposing unaltered lumps of the hydrate to the action of the emitted hydrogen sulphide, and by the chemical reaction induced by exposure to the air.

## PART II.

In order to arrive at an experimental demonstration of the various phenomena experienced by gas engineers in the course of the purification of coal gas from carbon disulphide, experiments were conducted in miniature, but to scale, as regards the relations between the rate of passage of the gas to be purified to the volume of the purifying material. The plan adopted was an imitation of the system of purification in use at the Commercial Gas-works, under Mr. H. E. Jones, which was described at length in his communication to the Institution of Civil Engineers already referred to. Instead of coal gas freed from hydrogen sulphide and carbonic anhydride, there was substituted hydrogen containing a quantity of sulphur, in the form of vapour of carbon disulphide, varying from 10 to 60 grains per 100 cubic feet; the average quantity of "sulphur," as organic sulphur compounds, in coal gas, after leaving the scrubbers,

§ Le Stazioni sperimentali Agrarie (Firenze), 1880, p. 104.

being 30 to 40 grains. According to calculations of Mr. Vernon Harcourt, from results communicated to him by several of the managers of London Gasworks, for every 1000 cubic feet of gas to be purified per hour, 20.3 to 110 cubic feet of lime are used. These figures were taken as the basis of calculation; and on a glass tower was measured off a volume of 0.01 cubic foot. This was filled with pure calcium hydrate of such consistency that it could be slightly moulded with the fingers. The rate of the gas to be purified was varied, according to the condition of the experiment, from 0.5 to 0.091 cubic foot per hour; the maximum rate corresponding to the minimum quantity of lime used per 1000 cubic feet per hour, and conversely.

The experimental plant was arranged as follows:—First, a Kipp's apparatus for the constant generation of hydrogen, which was freed from any spray of sulphuric acid by passing through bulbs containing water. The gas then flowed over a bulb-shaped tube filled with carbon disulphide; the neck of the tube being drawn out, and provided with a small pin-hole for the vapourisation of the liquid. The gas could then pass in one of two directions—viz., either directly into a glass tower filled with ferric oxide, or through the lime purifier, and thence through the ferric oxide. The object of the oxide was to absorb the hydrogen sulphide either as formed in small quantities by the action of the dilute sulphuric acid on commercial zinc, or as emitted from the purifier. The gas then passed into the colour-test apparatus of Mr. Vernon Harcourt.

Preliminary experiments were made to determine (1) whether the proportion of carbon disulphide vaporised by the hydrogen remained constant, under constant conditions of temperature, within the limits of time in which testings were made; and (2) to ascertain whether the proportion of sulphur indicated by the colour tests varied with the rate at which the gas was drawn through the test apparatus by the aspirator—the rate of passage of gas being estimated by the time occupied by the testing and the volume of water which had run out into the measuring cylinder. The results were found to be satisfactory. Before each set of experiments, blank testings were made; the bulb containing the carbon disulphide being temporarily removed, to ensure that the gas was free from all sulphur compounds. All the testings were conducted in duplicate. In the earlier experiments one-third of the calcium hydrate was converted into the sulphide. The material thus obtained was of a pale yellow colour, due to a slight oxidation. But as this gave unsatisfactory results as regards the removal of the carbon disulphide, another third was converted into sulphide, and the results were satisfactory. The following may be cited:—

**SERIES I.—Rate of Gas (approximately), 5 Cubic Feet per Hour.**

Composition of Gas.	Grains of Sulphur per 100 Cub. Ft.	Percentage of Sulphur removed.
(1) Sulphur as carbon disulphide present in gas .....	62	..
(2) After passage through calcium sulphide .....	44	.. 94.5

**SERIES II.—(Conditions as above.)**

(1) Sulphur as carbon disulphide .....	56	..
(2) After passage through calcium sulphide .....	nil	.. 100

**SERIES III.—(Conditions as above.)**

(1) Sulphur as carbon disulphide .....	217	..
(2) After passage through calcium sulphide .....	nil	.. 100

**SERIES IV.—Rate of Gas 0.67 Cubic Foot per Hour.**

(1) Sulphur as carbon disulphide present in gas .....	80	..
(2) After passing through calcium sulphide .....	81	.. 89.8

These results show that damp calcium sulphide is a fairly-efficient material for removing carbon disulphide. Similar series of experiments were conducted with a sample which had been "sulphided" by dry hydrogen sulphide (*vide supra*); but this absorbed not more than 66 per cent. of the carbon disulphide.

**SERIES V.—Rate of Gas, 0.5 Cubic Foot per Hour.**

Composition of Gas.	Grains of Sulphur per 100 Cub. Ft.	Percentage of Carbon Disulphide removed.
(1) Sulphur as carbon disulphide present in gas .....	25.7	..
(2) After passing through calcium sulphide .....	8.6	.. 66.1

**SERIES VI.—(Conditions as above.)**

(1) Sulphur as carbon disulphide .....	35.7	..
(2) After passing through sulphide .....	11.1	.. 64.0

**SERIES VII.—(Conditions as above.)**

(1) Sulphur as carbon disulphide .....	26.3	..
(2) After passing through sulphide .....	9.4	.. 64.0

**Effect of Temperature.**

In order to study the effect of temperature, the cylinder containing the sulphide was surrounded by a freezing mixture of ice and salt; and the activity of the material was decreased, as shown by the following results:—

**SERIES VIII.—(At 15° C.)**

Composition of Gas.	Grains of Sulphur per 100 Cub. Ft.	Percentage of Carbon Disulphide removed.
(1) Sulphur as carbon disulphide .....	20.8	..
(2) After passing through sulphide .....	7.2	.. 71.4

**SERIES IX.—(At -10° C.)**

(1) Sulphur as carbon disulphide .....	16.1	..
(2) After passing through sulphide .....	8.5	.. 58.0

This result explains in a further way the inactivity of purifiers in very cold weather. In this, as in all other observed cases, the rate of chemical change decreases with decrease of temperature.

But in all these cases the yellow colour gradually mounted up the cylinder; thus indicating the evolution of hydrogen sulphide, noticed in Part I.

**Effect of Various Gases.**

A series of experiments was made with the view of investigating the chemical changes induced by the passage of gases likely to be present in coal gas issuing from the scrubbers, on a sample of foul lime which had absorbed a considerable quantity of carbon disulphide, and assumed a uniform orange-red tint, characteristic of the basic calcium thioearbonate.

**SERIES X.—Hydrogen.**

**Rate of Passage of Gas (approximately), 0.5 Cubic Foot per Hour. Temperature, 15° C.**

(1) Hydrogen passing through ferric oxide, and thence over platinumised pumice .....	The lead syrup remained unaltered.
(2) Hydrogen passing through the thioearbonate, and thence over platinumised pumice .....	" "

The calcium thioearbonate is not decomposed by hydrogen at ordinary temperatures. Similar results were obtained with purified marsh gas.

**Hydrogen Sulphide.**—To study the effect of hydrogen sulphide, a Wolf's bottle with three tubulures was introduced into the apparatus, immediately after the washing-bulbs. This contained a dilute solution of hydrogen sulphide, the strength of which could be renewed from time to time by passing a few bubbles of the gas by means of the middle tubulure from a Kipp's apparatus. The hydrogen blowing over the

surface of the solution carried forward a small quantity of the gas, which was passed immediately into the colour-test, and estimated in the usual way. The experiment was repeated, the hydrogen sulphide being absorbed by the ferric oxide purifier.

#### SERIES XI.—Hydrogen Sulphide.

Rate of Passage of Gas (approximately), 0.5 Cubic Foot per Hour. Temperature, 15° C.

Conditions.	Grains of Sulphur per 100 Cub. Ft.
(1) Sulphur present as hydrogen sulphide; the platinised pumice being cold .....	100
(2) Do. after passage through the "sulphidised" lime and ferric oxide .....	Nil
(3) Same as (2); the platinised pumice being heated .....	10.2

From the above experiment it is seen that, whereas all the sulphur as hydrogen sulphide is removed by the sulphide of lime and ferric oxide, there is driven forward a small quantity of carbon disulphide, as indicated by its conversion into hydrogen sulphide on warming the bulb of the colour-test. The result is due probably to a local formation of calcium hydrosulphide and the decomposition of the thiocarbonate. It is in perfect accordance with the observations of gas engineers, who have noticed that, as the quantity of hydrogen sulphide passing into the calcium sulphide purifiers was greater or less, the efficiency of the purifiers was inversely diminished or increased.\*

To add confirmatory evidence, a series of experiments was conducted in succession. It was ascertained once for all that no carbon disulphide was present in the apparatus, and that all the hydrogen sulphide contained in the gas was perfectly absorbed by the sulphidised lime and ferric oxide.

#### SERIES XII.

Grains of Sulphur as Hydrogen Sulphide per 100 Cub. Ft.	Grains of Sulphur as Carbon Disulphide per 100 Cub. Ft., evolved by the Decomposition of the Thiocarbonate.
(1) 167 .....	(1a) 33.3
(2) 77 .....	(2a) 22.7
(3) 89 .....	(3a) 23.8
(4) 79 .....	(4a) 21.1

From these experiments it follows that the greater the quantity of sulphuretted hydrogen passing into the purifier, the greater the quantity of carbon disulphide eliminated. In fact, these results are precisely analogous to the well-known "gushes or discharges of sulphur" when the purifiers are worked on the Paterson or continuous system.

#### Effect of Carbonic Anhydride.

It has long been known that before the coal gas passes into the vessels, used for the removal of carbon disulphide, all the carbonic anhydride must be removed, inasmuch as this substance decomposes both calcium sulphide and thiocarbonate, with elimination of hydrogen sulphide and carbon disulphide respectively.† In order to ascertain the magnitude of these decompositions, under conditions likely to occur, the effect of hydrogen containing a quantity of carbonic anhydride equal to that present in coal gas issuing from the scrubbers (500 to 1100 grains per 100 cubic feet) was studied. The artificial gas was prepared by passing into a gasholder filled with hydrogen a few bubbles of carbonic anhydride, the proportion of which was determined by Pettenkoffer's well-known baryta-water method. The mixture, after passing through the washing bulb, entered the calcium sulphide purifier, and thence either directly into the colour test, or through the ferric oxide purifier, and then to the colour test. If the platinised pumice

be heated, and the gas passed through the ferric oxide, the amount of carbon disulphide eliminated is determined; but if the gas is not passed through the ferric oxide the amounts of hydrogen sulphide and carbon disulphide together are estimated. The difference between the former and the latter value gives the quantity of hydrogen sulphide. Two conditions are likely to occur in practice. In the one the foul lime purifier may contain unaltered calcium hydrate; in the other, the lime may be completely fouled. The effect of the carbonic anhydride under each of these conditions was observed. The results showed that in the former case carbon disulphide only is eliminated; the unaltered portions of the calcium hydrate absorbing all the hydrogen sulphide, and simultaneously a portion of the carbon disulphide.

#### SERIES XIII.

Lime Purifier containing Three Parts of Sulphide and Thiocarbonate, and One Part of Unaltered Calcium Hydrate. Rate of Gas (approximately), 0.5 Cubic Foot per hour; Temperature, 15° C.

Conditions.	Grains of Sulphur as Carbon Disulphide per 100 Cubic Feet.
(1) Gas passing through sulphidised lime and ferric oxide .....	3.15
(2) Gas passing through sulphidised lime only .....	2.78

#### SERIES XIV.—(Conditions as above.)

Grains of carbonic anhydride per 100 cubic feet, 118.3.	Grains of Sulphur as Carbon Disulphide.
(1) Gas passing through sulphidised lime and ferric oxide .....	2.3
(2) Gas passing through sulphidised lime only .....	2.2

The remaining one-fourth of the calcium hydrate was then converted into sulphide by hydrogen sulphide, the excess of which was blown out by a current of hydrogen before testings were made.

#### SERIES XV.—(Conditions as above.)

Grains of carbonic anhydride per 100 cubic feet = 351.	Grains per 100 Cub. Ft.
(1) Sulphur as carbon disulphide and hydrogen sulphide liberated .....	22.7
(2) Sulphur as carbon disulphide .....	3.0
Difference = hydrogen sulphide ..	19.7

#### SERIES XVI.—(Conditions as above.)

Grains of carbonic anhydride per 100 cubic feet = 417.	Grains per 100 Cub. Ft.
(1) Sulphur as carbon disulphide and hydrogen sulphide liberated .....	27.0
(2) Sulphur as carbon disulphide .....	3.9
Difference = hydrogen sulphide ..	23.1

#### SERIES XVII.

Grains of carbonic anhydride per 100 cubic feet = 780	Grains per 100 Cub. Ft.
(1) Sulphur as carbon disulphide and hydrogen sulphide liberated .....	31.7
(2) Sulphur as carbon disulphide .....	6.0
Difference = hydrogen sulphide ..	25.7

Then, under these conditions, not only is hydrogen sulphide emitted, but the proportion of carbon disulphide emitted is increased.

In conclusion the author wishes to record his best thanks to Mr. Vernon Harcourt for kind assistance and advice. He is also greatly indebted to Mr. Jones's paper for the suggestion of some of the experiments above detailed.

[The author illustrated, by experiments, the actual method employed for obtaining the results described in Part II. of the paper.]

## DISCUSSION.

The CHAIRMAN (Mr. D. Howard) said Mr. Veley's communication was a very interesting one; and the subject of gas purification was one with which the members were all in some way concerned. There were few points more important than the total removal of carbon bisulphide from gas; and he was old enough to remember when it was regarded as almost a hopeless task. The singularly-easy method whereby it was at present removed, the chemistry of which had been so ably explained, was one of those happy adaptations of a very simple process which was really amongst the most valuable discoveries in chemistry.

Professor FOSTER said there was one point in connection with this question, of the action of sulphuretted hydrogen on lime, which he did not think had yet been quite cleared up. Dr. Divers, in his admirable paper, gave a considerable amount of information with reference to the hydrosulphide and the hydroxy-hydrosulphide described by Mr. Veley.\* At the time he took occasion to note that if, by his statement, Dr. Divers meant that the treatment of calcium hydrate with sulphuretted hydrogen was attended with the production of hydrosulphide only, under the conditions which obtained in the ordinary lime purifier of the gas engineer, he could not agree with him. Like most men engaged in matters relating to coal gas, he had worked on this lime question; but all alike seemed to be in the dark until Dr. Divers's paper appeared. The subject of his own inquiry had then resolved itself into the action of sulphuretted hydrogen on pure lime, although he began with a large number of specimens of spent lime; the results being very similar to those of his predecessors—viz., entirely unsatisfactory. Dealing with commercial lime, he endeavoured to get at some knowledge of what happened when sulphuretted hydrogen was passed into it, commencing at the ordinary temperature, and keeping well within the temperatures which were produced by the chemical action of the sulphuretted hydrogen on the calcium hydrate. The result of his inquiry was to lead to the following conclusion:—That if calcium hydrate was treated with sulphuretted hydrogen in this way, under the ordinary conditions, this result (expressed empirically) was obtained— $\text{CaO} \cdot \text{CaS}_2\text{H}_2\text{O}$ . Expressed constitutionally (following Dr. Divers), the formula was— $\text{Ca}_2\text{HOCaHOHS}$ . The point was this—that such a compound only contained one-half the sulphur which Dr. Divers and Mr. Veley attributed to the compound in question. Dr. Divers stated in his paper that calcium hydrosulphide was produced in the lime purifiers. It might be that some of the conditions could be explained, because they all knew, from the experience of Dr. Divers and Mr. Veley, that hydrosulphide underwent splitting up into calcium hydroxy-hydrosulphide, with a production of calcium hydrate. What he wished to point out was (and it was a practical matter for gas managers) that, in the purifiers charged with calcium hydrate, the condition of things named would result. Speaking from memory, the compound contained 20 per cent. of sulphur. Another practical point was this: He had never met with a specimen of spent lime obtained in the ordinary way, and containing moisture, in a condition which had more than 10 per cent. of sulphur. Therefore, if a gas engineer followed the formula as he had given it—and he believed it to be quite possible—if he tried to realise this condition of things, he would never ordinarily reach more than 20 per cent.; and however long he tried he would never succeed in getting much beyond this. The

action was a perfectly definite one. If a tube containing calcium hydrate were taken, and if sulphuretted hydrogen were then passed—a dryer and an absorber of oxygen being arranged immediately—the action was quite progressive. Hour after hour the progression of the sulphuretted hydrogen could be seen, and as long as there was a particle of lime in front no sulphuretted hydrogen passed through the tube. Sulphuretted hydrogen might even be passed through for some time, and after it escaped freely, if the compound were then removed and dried over sulphuric acid such figures as these would eventually be found— $\text{CaO} \cdot \text{CaS}_2\text{H}_2\text{O}$ . He believed that Dr. Divers's statement and his own experience might be reconciled. All he contended was that, in the lime purifier, as ordinarily charged, the formula which he had given was nearly the actual condition of things that would obtain under such circumstances. If, therefore, one used the constitutional formula—showing a so-called molecular compound—they could understand how the action on bisulphide of carbon took place. In relation to the paper, many other questions arose which he would have liked to go into; but, after all, this was the practical point—that one could not get anything like the percentage of sulphur into the calcium hydrate which the able experiments of Dr. Divers had incidentally led people to believe. It might possibly be done at a very low temperature, but unless the gas engineer realised such conditions he would fail in his task. From a money point of view, it meant, of course, that if calcium hydrate were used for the purpose of taking out sulphur, there again arose the question of expense in effecting the object, because he could in this way never get more than such a ratio, unless he passed sulphuretted hydrogen for a very prolonged time. He had specimens of lime obtained by passing sulphuretted hydrogen, taking out the mixture and allowing it to be again treated; but he never obtained, under these conditions, with ordinary dry hydrate, 1 atom of calcium to 1 of sulphur.

Mr. C. W. FOLKARD said it had been remarked by the last speaker that, in the ordinary process of purification in gas-works, it was impossible to get more than about 50 per cent. of the lime transformed into sulphide. Two years ago he published in the *Chemical News*, the results of some experiments he had conducted on a small scale, which showed very plainly that this was the case; and he frequently analysed the material coming from the lime purifiers, and had never been able to get more than 51 per cent. transformed—it varied from about 42 to 51 per cent.—even after the gas containing sulphuretted hydrogen had been passed until a large quantity had come right through the purifier for several days. He thought it exceedingly probable that this was due to a matter which had been referred to earlier in the evening—viz., to the action of mass—because the crude gas contained an exceedingly small proportion of sulphuretted hydrogen. He could understand that, if pure sulphuretted hydrogen were passed into slaked lime, it was quite possible that the reaction would be such as to transform the whole of the lime into calcium sulphide, instead of getting a molecule of calcium sulphide to combine with one of undecomposed lime, which was undoubtedly the form in which the reaction took place in ordinary gas-works. He would ask Mr. Veley to tell them exactly how he prepared the sample of slaked lime. He had been careful to proportion the amount of gas passing through to the bulk of material. But there was another small point which made a great deal of difference in these matters, and it was this—that the depth of material was not the same. In an ordinary purifier the material would be something like 24 inches deep, and

\* See Journal of Gas Lighting, Sept. 9, 1881 p. 471.

therefore the gas would pass very much more rapidly past a given particle of lime. Mr. Veley had properly proportioned the cubic amount of purifying material to the volume of gas, but had not the same surface area as existed in gas-works. He (Mr. Folkard) should think that it would be about one-eighth or one-tenth, and this would make a vast difference in the result. It was well known that if the purifiers were three or four times the usual area, the purifying action was much greater, whereas Mr. Veley's experimental purifier had about one-tenth the area usual in gas-works. It had been found, in experimenting on a small scale, that almost anything would take out carbon disulphide, therefore these small experiments were always liable to lead to error.

Dr. P. F. FRANKLAND asked Mr. Veley whether he had the proportionate amount of sulphur compounds in the gas as well as the total quantity of gas. If this were a question of mass action, as Mr. Folkard suggested, it was, he said, obvious that very different results would be obtained according as a larger or a smaller proportion of sulphide of carbon was used respectively to a smaller or larger proportion of gas.

Mr. VELEY, in reply, said he had conducted the experiments in this way: Starting with a known quantity of lime, he passed the sulphuretted hydrogen into it, and weighed the material, and also the water which was formed. Making a synthesis of the product, he had shown that, starting with a known weight of lime, and passing in sulphuretted hydrogen until all the change was complete, as shown by the fact that the continuation of the passage of the gas merely caused a dehydration of the material (that was to say, the loss of the tube containing the lime was exactly equal to the gain found in the water collected) the result was—

Making analyses of this material, he found the result coincided almost exactly with that of his synthesis. Even according to Professor Foster's own admission, substances examined by him were really admixtures of calcium sulphide and unaltered lime; for he himself said that if he took out the lime, shook it about and otherwise disturbed it, put it back again, and then repeated the action with sulphuretted hydrogen, he could get a larger quantity of the gas absorbed.

Professor FOSTER said this was scarcely so. What he wanted to point out was that, when sulphuretted hydrogen was passed into slaked lime at the ordinary temperature of a room, the affinity or attraction was most marked, and the sulphuretted hydrogen progressed most slowly, so that not a particle of lime escaped its action; then the action stopped, and the sulphuretted hydrogen passed most freely. If the lime were taken out and rubbed up, and then had a dose of sulphuretted hydrogen given to it, the percentage might be slightly increased. Whether the increase in the action of the lime was due to oxidation, to the rubbing up, or to the hydrolysis through the presence of moisture, he could not say; but the action, in the first instance, was a definite one, and seemed to stop at a certain stage.

Mr. VELEY said he had never arrived at this stage, but always found it go on to a further one. If the experiment at this stage were carried on at the ordinary temperature for many days, then the result was complete. He took it that Professor Foster's results were due to what he (Mr. Veley) had always found an exceedingly practical difficulty—damp calcium sulphide caking round, and thus enclosing nuclei of unaltered lime. It was obvious that if a certain amount of calcium sulphide caked together, as it would, there would be also included in such a caked mass quantities of unaltered lime. The great

practical difficulty in working was to avoid this caking together of material. Mr. Folkard had inquired how he prepared his slaked lime. For these experiments he started with a known quantity of purified calcium oxide, from which all impurities (such as iron, silica, barium, and strontium) were removed. He hydrated it in an apparatus devised to eliminate all traces of carbon anhydride, and then succeeded in converting a certain weight of calcium oxide into the theoretical quantity of calcium hydrate (the figures were given in the paper). This material was put into a tube, and perfectly dry sulphuretted hydrogen, from which all traces of oxygen had been carefully removed, sent in. It did not follow that, when some sulphuretted hydrogen passed over, the reaction was therefore complete; in fact, the reaction would go on slightly even, for a long time after volumes of sulphuretted hydrogen passed through the lime purifier, owing, as he took it, to the caking together of these damp masses of calcium sulphide. For these experiments pure lime was mixed with water so as to form a substance of similar consistency to that used by gas engineers. He had made many experiments, varying the rate and the proportion of carbon disulphide, and under these conditions all the carbon disulphide had been removed. If, then, it was all removed, taking the minimum volume of lime with the maximum quantity of gas containing the largest quantity of carbon disulphide likely to be present in practice—a *fortiori* this would be removed when a lower rate was taken, and when the gas contained a smaller proportion of carbon disulphide. He could not agree with the suggestion of Mr. Folkard that it was proper to take the relation of the area of the purifying material to the volume of gas to be purified. It appeared to him that in this case two different kinds of quantities were being dealt with—square feet of purifying material and cubic feet of gas to be purified, and this seemed to be rather an irrational way of looking at it. They must be put in the same terms—viz., volume of purifying material to volume of gas; for, even although the gas to be purified passed over, it also passed through the cubic contents of the purifier. Thus he thought the proper relation to be taken was that of volume to volume. When such a purifier had been in action for some time all the sulphuretted hydrogen was gradually driven off, and the lime from this purifier merely possessed the odour of carbon disulphide, not the peculiar disagreeable odour of ordinary foul lime.

## THE COMPARATIVE EFFICIENCY OF VARIOUS MODES OF TREATING LIQUIDS WITH GASES.

F. HURTER, PH.D.

WHEN our engineers are asked to erect any structure, they calculate the probable weight which it has to

carry, or the stresses it is subject to; they take out of their pocket a valuable thing called a "Molesworth," or some other book filled with formulae, and by means of them calculate the dimensions of their structure. Their skill and experience is employed in choosing and combining the materials and the factors of safety, and they trust the rest to Molesworth and providence. I am told that most of the structures of the chemical works in Widnes are based upon these formulae collected in Molesworth. Why can we trust so implicitly to such formulae? Simply because they are the most concise record of the experiences of our most eminent engineers; and not only a record of their experience, but also of their success in tracing out the causes of the phenomena they have observed.

In the construction of chemical apparatus, as far as the strength is concerned, the same facility is afforded; but as regards every other particular we are left entirely to our fancy, or in the case of long experience, to that second sight which is gradually and unconsciously acquired. But with the termination of the career of many a successful man terminates also his whole experience. Owing to the fact that his experience was not in a form sufficiently concise to be readily transmitted to others, that it was not formulated experience—it is entirely lost. I have frequently felt the want of such guides to the best form and general construction of new apparatus, as the engineers possess for finding the dimensions, when the general form is given to them. I have consequently always been anxious to collect isolated experiments under a general formula. I have tried to collect the whole of the experience of myself and others of vitriol chambers in such a single formula, and I brought the results of such an attempt before this Society some years ago.

To-night I wish to discuss the comparative efficiency of various modes of treating liquids with gases. I meant to discuss all the modes now in use, but I found the subject too large for one paper. I have decided, therefore, to discuss only one class of apparatus, but so that the paper will form an independent whole, and I may, at some future meeting, if it be your pleasure, discuss the remainder of the subject.

# I.

The treatment of a liquid with a gas has usually one or both of two ends in view: either we wish to saturate completely a liquid with one of the constituents of a gaseous mixture, or we want to deprive the gas wholly of one of its components, or we are obliged to accomplish both the saturation of the liquid and the complete absorption of one of the gaseous substances constituting the mixture. Sometimes a liquid is treated with a gas for the purpose of removing from the liquid a volatile compound.

For whichever of these purposes we treat a liquid with a gas, the mechanical part of the problem is always the same: we must bring the gas into intimate contact with the liquid. This intimate contact can only be brought about by the expenditure of energy; we have to do a certain amount of mechanical work. But the problem of treating liquids with gases is not so simple as to resolve itself merely into a discussion of how to produce the intimate contact with the least expenditure of work; we might produce a very intimate contact very cheaply, but afterwards waste the contact by otherwise badly arranging our apparatus—i.e., obtain a very small effect in spite of the intimate contact—if we paid not sufficient attention to the chemical part of the problem.

Before we can speak either of the mechanical efficiency of a piece of apparatus producing the necessary contact, or of the efficient utilisation of the contact so produced, we must have some measure for the contact itself—we must have a unit of contact.

The amount of absorption which will take place between a gas and a liquid will depend entirely upon the number of molecules of the gas which will, during a given time, impinge upon the liquid—i.e., it will be proportional to the extent of the border-surface between the liquid and the gas, to the number of molecules which impinge upon the unit area of this surface in unit of time, and to the length of time during which these conditions obtain. As the number of molecules which impinge upon unit-surface in unit of time is proportional to the pressure of the gas, the pressure itself may be substituted for that unknowable number. I shall, therefore, define (for the purposes of my comparison of the efficiency of various apparatus) one unit of contact to mean that unknown number of molecules which would impinge upon unit area in unit of time if the gas exerted unit pressure.

For technical reasons I choose the following units:—As unit area, the square meter; as unit pressure, 1 meter of water; as unit time, 1 second. So that 1 unit of contact means the number of molecules of a gas which would impinge in one second upon 1 square meter area if the gas were under a pressure of one meter of water.

Five units of contact might be obtained from three different sets of conditions: we might have five square meters' area acting during one second with the gas of one meter pressure, or we might refer to one square meter acting for five seconds with a gas of one meter pressure, or we might refer to a surface of one square meter maintained for one second, the gas being under a pressure of five meters of water. In each of these cases the actual number of molecules impinging would be exactly the same, and, consequently, if in all three cases the chemical condition of the liquid and the gas were the same, the rate of absorption would also be the same.

The mechanical efficiency of any piece of apparatus can thus be measured by the number of such units of contact which it yields for a given expenditure of work, say for the expenditure of one kilogrammeter.

All apparatus for bringing into contact liquids and gases can be divided into three classes, according to the method employed for producing the contact-surface.

(1.) The gas, divided into small bubbles, passes through a column of liquid.

(2.) The liquid, divided into fine drops, falls through a column of gas.

(3.) Solids, with extensive surfaces and interstices, are covered with the liquid, the gas filling up the interstices.

A comparison of the efficiency of these various classes of apparatus is very difficult, and I have not completely solved the problem; but what I have done will, I hope, form a foundation for other investigators, and form, to some extent, a guide to the choice of apparatus for any given case.

That such a choice is sometimes extremely difficult, is illustrated by the various apparatus which various technologists prefer for one and the same process. Thus, for instance, I found when I came to this country, just at the time when Mr. Weldon's process for the recovery of manganese was about to be introduced, one chemist attempting to subdivide the liquor in which the manganous oxide was suspended into fine spray, and allow it to fall through air. In a patent (not Mr. Weldon's) I found a proposal to project that liquid into the air by means of paddle-wheels. Then we have Mr. Weldon's own solution of the problem—the best—which consists, as you are well aware, in injecting the air into the liquid.

I shall confine my remarks to-night to apparatus of the first class—that where the gas is divided into fine

bubbles, and made to pass through a column of liquid.

This method of treating a liquid with a gas has, at first sight, the great disadvantage, that the mechanical power required for the production of the contact is very great. Thus, for instance, it requires the expenditure of 998 kilogrammeters to propel one cub. meter of gas through a column of water one meter deep; so that the work done in propelling one kilogramme of gas through one meter of liquid is equal to that of lifting one kilogramme of water 1000 meters high. When, in addition to this high expenditure of work per cub. meter of gas, we consider that every cub. meter of liquid has usually to be treated with an enormous bulk of gas varying in different technical processes from 200 to 20,000 cub. meters, we need not be surprised that now and then attempts are made to avoid using this apparently very costly method.

The apparatus used for this mode of treating liquids with gases is usually extremely simple, and it cannot be too simple. In most cases the apparatus consists of a vertical cylindrical vessel holding the liquid. At the bottom of the vessel is usually placed a system of pipes ending in numerous small orifices, so as to spread the gas and distribute it equally over the area of the vessel. The gas is delivered by an air pump, which compresses it to a pressure slightly greater than that due to the depth of the column of liquid through which the gas has to rise. In other cases the vessel is closed at the top, and the space over the liquid is exhausted, so that the gas is drawn through the liquid instead of forced through. In other instances, for example, in the apparatus Mr. Chance used for carbonating the mixture of magnesia and calcium chloride, the vessel is closed at the top, and provided with a loaded valve, so as to enable the liquid to be treated under a much greater pressure than that due to the column of liquid contained in the vessel. In all these cases, the work to be done, and the result obtained, are very different.

One great difficulty presents itself at once when we wish to deal arithmetically with the question of efficiency of this kind of apparatus. It is impossible to measure the surface which the gas bubbles present to the liquid; we can only make some approximate estimation. But it is possible to ascertain how the surface of the gas bubbles varies under different circumstances, such as depth of liquid, nature of the liquid and the gas. I have made this the subject of a few experiments. The first question which I attempted to answer was, How does the size of a gas bubble issuing from a given orifice vary as that orifice is immersed to different depths in the same liquid? I found that the diameter of the bubble was always the same, however great I made the depth of the column. I varied the depth of the column from 0.2 meters to 10 meters, and I found no greater difference than 1 per cent. in the value of the diameter of the bubbles. I repeated the experiments with various orifices, which, of course, gave bubbles of different diameters; but one and the same orifice always gives bubbles of one diameter, whatever the depth of the liquid above the orifice may be. The same result is obtained whether the orifice is simply the end of a straight pipe, or whether it is a pin hole in a sheet of platinum; the bubbles from the pin hole will be smaller, but they are all equal to, and independent of, the column of liquid above. I also found that for a given orifice the size of the bubbles was independent of the nature of the gas. Whether the gas was hydrogen, air, coal gas, or carbonic acid gas, the bubbles from the same orifice were equally large. The only great alteration in the size of the bubbles is produced by a change in the liquid itself. A very small addition of alcohol to water will

materially reduce the size of the bubbles formed by a given orifice.

These experiments lead to the conclusion that the size of the bubbles obtained from any gas by passing it through a given distributor is independent of the pressure above the distributor. Of course, as the bubbles rise they expand, and the amount of this expansion will depend upon the height of the column. But at the point at which the bubbles leave the distributor, their diameter will only depend upon the size of the openings of the distributor, and upon the viscosity of the liquid.

The next question which I tried to settle by experiment was, How do the bubbles move upward, is their velocity accelerated, or retarded, or uniform? And, if possible, I wanted to obtain its magnitude.

The velocity of bubbles in a wide glass tube I found so small that, by means of a metronom beating 240 beats a minute, I could obtain some approximate idea of the velocity. I found no appreciable acceleration: the motion was, as far as I could judge, perfectly uniform. I ascertained the velocity to be about 0.3 meters per second, or not quite one foot per second. I felt, however, that the results of so rough an experiment would not form a secure basis for any important calculations. Conclusions from an experiment, where one bubble was made to rise, and only one, through a quiescent liquid, might not apply to a case where thousands of bubbles are on their way through a liquid in violent agitation, as we have it in a Weldon oxidiser. I therefore endeavoured to ascertain the average velocity of such bubbles in a Weldon oxidiser. This, at first sight a difficult problem, is really very easily solved. Owing to the slow motion of bubbles through the liquid, there are a considerable number of them on their way through the liquid at any moment, they displace a certain amount of liquid, consequently the level of the liquid rises. If we measure the amount which the liquid rises, ascertain at the same time the rate at which the gas is pumped through the liquid, also the height of the liquid when quiescent, and the area of the vessel, we have all the data needed for calculating the average velocity of the air bubbles in the Weldon oxidiser. Clearly the amount of liquid displaced gives us the amount of gas in the liquid at any moment, from the distributor to the surface of the liquid. Fancy you followed with your eye the bottom layer of bubbles as they gradually rise: by the time this layer has arrived at the surface, the whole vessel has been supplied with as much gas again as it contained when that layer was at the bottom; therefore, the time which it takes for the air pump to supply that gas is also the time which that layer of bubbles required to rise to the surface.

If  $D$  is the depth of the liquid when quiescent, and  $d$  the amount it rises, when gas is blown through it at the rate of  $C$  volumes per second (measured at the average pressure in the liquid) and if  $A$  is the area of the vessel, the amount of the liquid displaced will be  $A.d$ , the number of seconds which it will take to deliver that amount will be  $\frac{A.d}{C}$  and in  $\frac{A.d}{C}$  seconds

the gas bubbles rise through the total height  $D+d$ , consequently their velocity is

$$v = \frac{C(D+d)}{A.d}$$

I will give the results of one such experiment, which serves as a numerical example. An oxidiser was charged to a depth of 15 feet, it had an area of 100 square feet: air was blown into it at the rate of 14.8 cubic feet (measured at a pressure of  $\frac{7}{8}$  feet of liquid). I found the charge to rise 2.66 feet. Thus the displacement was 266 cubic feet, and the time necessary

to deliver this amount 18.3 seconds, this being also the time necessary for the bubbles to pass through a column now 17.66 feet in height. The average velocity is thus  $\frac{17.66}{18.3}$  or .95 feet per second. This

shows that the average velocity in such apparatus does not differ materially from that found in the experimental tube. (Before passing on with my subject, I will just draw attention to the fact, that the velocity of bubbles being taken at 1 foot per second approximately, the formula just given may be used for calculating the amount which a liquid will rise in any vessel when gas is blown through at a certain rate; the formula for that purpose assumes the form

$$d = \frac{D.C}{v.A.C}$$

Thus my experiments made also with various depths of liquids have shown me that for practical purposes the velocity of these bubbles is nearly constant, and about .93 meters per second.

Owing to the fact that the diameter of the bubbles is always the same whatever the pressure is, one cubic meter of gas measured at atmospheric pressure will not always yield the same surface in the same distributor, that depends upon the depth of the column of liquid. For although the bubbles are always of the same diameter, the weight of gas contained in one bubble is of course greater the greater the depth of the column of liquid.

As the bubbles rise through the column of liquid they expand, and thus enlarge their surface. At the same time the pressure diminishes. It is not difficult to calculate the total number of units of contact thus produced for each bubble in rising. If this is multiplied by the number of bubbles which would make up one cub. meter of gas at ordinary barometric pressure, a formula is readily found, which will give the number of units of contact produced per cub. meter of gas.

For the three modifications of apparatus in which bubbles are made to rise through the liquid, these formulae are the following three:—

(1.) For blowing gas through a column of depth  $D$ , the barometric pressure being  $b$  meters of the same liquid, and the velocity of bubbles .93 meters a second  $k$  the co-efficient of distributor—i.e., number of square meters it produces per cub. meter of gas, when the bubbles issue at atmospheric pressure.

$$(1) \text{ Units of contact per } \frac{10}{1} \text{ Cub. meter gas } \dots = \frac{10}{1} k \cdot b^2 \left( 1 + \frac{D}{b} - \sqrt{\frac{b}{b+D}} \right)$$

(2.) If the gas is pulled through the vessel by a vacuum pump, the symbols having the same meaning—

$$(2) \text{ Units of contact per } \frac{10}{1} \text{ Cub. meter gas } \dots = \frac{10}{1} k \cdot b^2 \left( 1 - \left( \frac{b-D}{b} \right) \sqrt{\frac{b-D}{b}} \right)$$

(3.) If the gas is compressed and passed through a column of liquid of depth  $D$ , and allowed to escape through a loaded valve maintaining an absolute pressure  $p$  at the surface of the liquid, the units of contact will be—

$$(3) \text{ Units of contact per } \frac{10}{1} \text{ Cub. meter gas } \dots = \frac{10}{1} k \cdot b^2 \left( \left( D+p \right) \left( 1 - \sqrt{\frac{p}{p+D}} \right) \right)$$

Such formulae in themselves convey to those not accustomed to read them no information whatever. I shall, however, give below a numerical comparison, which will show a striking difference in the cost of the three methods.

I have defined the efficiency of a piece of apparatus as the number of units of contact produced per kilogrammeter of work spent. If the amount of work to be done per cub. meter of air is known, we have only to divide the units of contact by the number of kilogrammeters to obtain the efficiency.

Supposing, in the first instance, we had a vessel holding 4 meters a liquid of sp. gr. 1.03, for which  $b=10$ , at the bottom of which we had a distributor yielding bubbles of 6mm. diameter which yields per cub. meter 1000 square meters of area, so that  $k=1000$ . The number of contacts which would be obtained—

1. If the vessel is open at top, and the gas forced through, it would be according to formula (1) 126,523 per cubic meter.

2. If the vessel is closed at top, and the gas drawn through by a vacuum pump, according to formula (2) 123,485 per cubic meter.

3. If the vessel is closed at the top, and the gas escapes through a loaded valve at a pressure of 1 atmosphere = 14.7lb. to the square inch = 29.4lb. absolute or—20 meters of our liquid, we have 129,475 per cubic meter.

These numerical results show that as far as the intimate contact is concerned, the same distributor will produce very nearly the same number of contacts whichever way it is applied. I discovered this fact—viz., that a given distributor produces the same result with the same height of column absolutely, whether the pressure above that liquid be 35lb. to the square inch or *nil* first, on experimenting on the large scale with a column of liquid 10ft. deep, containing caustic alkali which had to be carbonated. The percentage of carbonic acid absorbed is independent of the pressure of the carbonic acid gas, whichever of the three modes of applying gas to the liquid is chosen. But when we come to consider the power employed to produce this contact, we find it for the three cases to be:—

1. For simply blowing the gas through four meters' depth of liquid per cubic meter of gas, 3643 kilogrammeters.

2. For simply pulling the gas through four meters of liquid, 4894 kilogrammeters.

3. For keeping the liquid under a pressure of one atmosphere . . . 10,274 kilogrammeters.

The efficiency of the apparatus is therefore:—

No. 1.	31.73 units per kilogrammeter.
No. 2.	23.23                   "                   "
No. 3.	12.60                   "                   "

These results show that the method of simply blowing air through a liquid is by far the cheapest of the three. Theoretically, the cost decreases as the column of liquid is increased, for methods one and three. Thus for 10 meters' depth of liquid, the efficiency of Nos. 1 and 3 become—

No. 1.	38.12 units of contact per kilogrammeter.
No. 3.	23.19                   "                   "

but practically the efficiency becomes less and less, owing to the difficulties which present themselves when gases have to be pumped against very high pressures.

The efficiency of the second modification diminishes very rapidly as the column is increased in height. That method is always to be avoided whenever it can be avoided. It is usually only employed where corrosive gases have to be absorbed, so as to avoid contact between the propeller and the corrosive gas.

There is one great drawback in all three modes: it is difficult to have a perfect counter-current, which for most chemical reactions is of very great advantage. By counter-current, I mean two streams moving in opposite directions, so that the saturated liquid leaves the apparatus where the fresh gas enters; whereas, the exhausted gas leaves the apparatus where the fresh liquid enters. This cannot be arranged to perfection with the method of gas bubbles, but in every other respect that method is little inferior to any.

## DISCUSSION.

In answer to questions, Dr. HURTER said that the pressures mentioned in his paper were absolute, and included barometric pressure; thus, he would call an absolute pressure of gas 4, which was capable of overcoming a column of water 4 meters in height.

Dr. CAMPBELL BROWN, while admitting that the paper was a model of philosophic argument and close reasoning, felt that the results arrived at were certainly unexpected. He would like to know whether air and water only, or whether soluble gases, such as chlorine, had been used; as the latter would complicate the results, but at the same time render them more valuable.

The CHAIRMAN asked how the force was measured in the case of a vacuum.

Mr. THOMPSON asked whether the size of the bubbles bore any ratio to that of the apertures? Also, supposing that an excess of force above that necessary to overcome the column of liquid were used, would the velocity of the bubbles be materially increased? In making some silicofluoric acid a short time since he had found that when he inserted his delivery pipe under mercury covered by water, the bubbles, which at first were large, diminished rapidly in size, until at last, when the gas became pure, they were reduced to very small dimensions.

Dr. HURTER, in answer to the Chairman, said that his figures were theoretical; in practice this efficiency was never realised, and the force required vastly exceeded that deduced from calculation. In answer to Mr. Thompson's question as to the size of the bubbles, he had not as yet satisfactorily determined their relation to that of the apertures. As regarded velocity, force above that required to overcome the pressure of the column was useless, as friction soon reduced any extra velocity so obtained to that of ordinary floatation; as regarded silicofluoric acid, as the gas increased in purity the bubbles diminished, until, with pure gas, they saw no bubbles at all.

Dr. HEWITT said that the late Dr. Angus Smith had been in favour of absorbing hydrochloric acid by means of a spray, and had shown him a design of apparatus to effect absorption by such means. Dr. Hurter evidently dissented from this notion. If, then, some definite law could be established, these questions would cease to become mere matters of opinion.

The CHAIRMAN said that the meeting were much indebted to the author for his valuable communication. He must confess his surprise at the figures given for the disproportion between the amount of force expended when gas was passed through a liquid in the one case, and presented in the form of spray in the other. He had always been in favour of the former method, but had no idea that the difference in cost was so great. Corrosive gases, however, required special methods of absorption. Many patents had been taken out for absorption in the form of spray, but it was well that manufacturers should be made aware that such methods involved great cost.

MEETINGS, SESSION 1885-86.—First Tuesday in each Month, at 7 P.M.

December 1.—A. H. Allen—"Further Notes on the Chemistry and Analytical Examination of Fixed Oils."  
Watson Smith—"The Violet Stains appearing on Sized Cotton Cloth" (*Experimentally Illustrated*).  
Notices of papers and communications for the meetings to be sent to the Local Secretary.

The opening meeting of the session was held in the Chemical Club Rooms at the Victoria Hotel, on Tuesday evening, 3rd November. The Chairman (Sir Henry E. Roscoe) in the chair.

The CHAIRMAN, after congratulating the members on the convenient situation of their meeting room, and on the active and promising condition of their Section, proceeded to point out the success achieved by members of the Society at the International Inventions Exhibition. The award of gold and silver medals in such large numbers to members of our Society was a very satisfactory state of things, as it betokened activity and showed that in the essential conditions of originality and of practical power the industrial chemists of England were not behind those of other countries. He then alluded to the great loss which the Society had sustained in the lamented death of their late President, Mr. Walter Weldon, and paid a well-deserved tribute of affectionate respect to the memory of one who had raised high the standard of science in its applications to the most important of our national chemical industries, and whose name would for ever be honourably associated with those industries, and with the Society which he helped to establish and did so much to adorn.

## NOTE ON ANTIMONY COMPOUNDS USED IN DYEING AND PRINTING.

BY B. W. GERLAND, Ph.D.

THE use of aniline colours in cotton dyeing and printing was largely extended by the introduction, through Messrs. Brooks & Co., of this city, of tartar emetic for fixing baths. The efficient constituent of the tartar emetic is antimonious oxide, which forms an insoluble lake of great resistance with the colour-tannate. The other constituent, bitartrate of potass (a rather costly substance, and likely to become dearer in consequence of the spread of the vine louse and increased demand), only serves to keep the metallic oxide in solution, and is lost with the waste waters. As the metallic oxide only amounts to 43.7 per cent. of the salt, its price in this form is very much enhanced. At the time, tartar emetic was the only compound of antimony in the market possessing the required qualities, and efforts were now made to discover one combining cheapness with these properties. As the outcome of these we have now two substitutes that are largely sold. One is the fluoride of antimony proposed by Mr. S. Mellor, of the Magnesium Metal Company, and manufactured in three forms by this firm—the acid and the neutral liquids, and the third as a white crystalline powder. The latter dissolves readily in boiling water, and like the others, can be diluted with water without separation of antimonious oxide. I am informed that of all antimony preparations these are the cheapest, and give satisfaction in the absence of light colours and ultramarine, which is discharged even by their dilute solution. I was anxious to experiment upon these fluorides, but the samples kindly sent by the Company only arrived yesterday. The other substitute for tartar emetic is the double salt of antimonious and potassic oxalate, supplied largely by Messrs.

Rudolph Koepp & Co., of Oestrich on the Rhine. They submitted this preparation to the judgment of Dr. Noelting, Professor of the School of Chemistry in Mülhausen, and received a very favourable report. According to this, the double oxalate did not only do the work as efficiently and as well as the tartar emetic, but it could, moreover, replace the latter weight for weight, although containing only a little over one-half the quantity of antimony. Dr. George Hirzel, of the Augsburg Printworks, instituted comparative trials between the oxalate and tartrate, and arrived at results differing widely from Noelting's (*Chem. Zeit. No. 41, page 325*). Noelting's reply soon followed, and as this enters fully upon all points, and gives also the opinions of Mülhausen printers, I cannot do better than lay a full extract of the same before you.

Hirzel mentioned trials on a large scale with printed pieces, which were fixed in baths containing respectively 10grm. tartar emetic, 10grm. antimony oxalate, and a third containing 19grm. of the latter per litre. The quantity of antimony in this bath was equal to that of the 10grm. tartar emetic bath. The pieces taken through the tartar emetic bath showed the fullest and brightest colours; those fixed in the weaker oxalate bath were weaker in colour, and even the colours of those which had been through the stronger oxalate solution were not equal in depth to the first lot. Similar results were obtained in a neighbouring printworks, and there a want of brilliancy in the colours was noted in the pieces fixed with the oxalate in comparison to those fixed in the tartrate. No better results were obtained by adding chalk, soda, or other neutralising agents to the fixing baths. Noelting, after referring to the results obtained in his laboratory, states that these have been completely verified in the Mülhausen Printworks, where the antimony oxalate is now used regularly, and explains the greater efficacy of the antimonious oxide in the oxalate by the greater inclination to disassociation of the latter. The fixation of the tannin is consequently quicker and more complete, but the baths are sooner exhausted, which, however, is an advantage, since the tartar emetic baths have often to be renewed before exhaustion, in consequence of having become fouled by colours stripped from the prints. The oxalate, according to the experience of Mülhausen dyers, can also be used for uni-dyeing, where the cloth mordanted with tannin is taken through the antimony bath and then dyed. In this case the oxalate also replaces an equal part of tartrate. Mr. Felix Weber, in a paper on comparative trials of antimony preparations, laid before the Chemical Committee of the Industrial Society of Mülhausen, pointed out the applicability of the antimony oxalate in every case. Noelting accounts for Hirzel's unfavourable results by the large quantities of oxalate used in the trials—viz., 10grm. and 19grm. per litre, whilst 5grm. is quite sufficient, and is supported herein by the experience of colourists, who find that such strong solutions yield worse results than weaker solutions, and that, specially in steam colours, the colours associated with tannin suffer. The statement of Hirzel's that the colours fixed by the oxalate are less brilliant and fast than those fixed by tartar emetic, is contrary to the experience of Mülhausen. The separation of insoluble basic antimony oxalate complained of by Hirzel has no disadvantage, since its precipitate fixes the tannin perfectly. Trials laid before the Chemical Committee by Mr. A. Kesters, repeated and confirmed by Mr. Weber, prove that freshly-precipitated antimonious oxide suspended in water, causes a complete fixation of tannin. Noelting does not expect that a few unfavourable results will cause the antimony oxalate

to be abandoned, after having become of general and extensive use among the printers of Mülhausen, and winds up his reply with the advice to practical men—"Try for yourselves."

This advice is to be taken to heart by printers and dyers most particularly. In these arts we have to deal with conditions and forces of which our knowledge is at best hazy, and speculations based upon such foundation can only become of value when tested by experiment.

As regards the fixation of colour tannates by tartar emetic, it is asserted that the antimony of the latter combining with the tannate forms an insoluble compound, an antimony lake similar to baryta being precipitated by sulphuric acid. That this is not so, but that other forces, perhaps attraction of the fibre, come into operation is evident from the following observations:—

A solution of tartar emetic, ten to 1000, is precipitated by a strong tannin solution, one to five, but not by one of one-tenth that strength.

A solution of the oxalate, fifteen to 1000, containing the same amount of antimony (see analysis below) is still precipitated by the weaker tannin solution. But a solution of three to 1000 is precipitated only after some time.

The colours, at least some, combine with the antimonious oxide, forming insoluble compounds in solutions of both the oxalate and the tartrate, but the limit of dilution is in this case even less favourable than with tannin. The presence of gum does not assist the separation of the antimony tannate. It is, however, easy to precipitate every trace of antimony from the weakest solution of the oxalate or tartrate by means of tannin, and *vice versa*, by adding a small quantity of some neutral salt—for instance, sodium chloride. This precipitate is insoluble in water and in an excess of the antimony solution, but soluble (and this is of great importance to the fixing process) in an excess of tannin. Considering these experiences, I recommend for the fixation of tannin or tannin colours in antimoniacal baths an addition of common salt, either to the colour or to the bath, and expect that from two to five per cent. of the water will be found sufficient.

In conclusion, let me add the result of an examination of the oxalate in crystals, received from Messrs. Koepp & Co.

These crystals are well formed and transparent. In the steam bath they soon become opalescent, then opaque white, with mother-of-pearl lustre, and continue to lose weight for a very long time (14 hours for 15grm.). No further loss occurs at 150°, and no oxalic acid is disipated at that temperature. The composition agrees with that of Souciay and Lossen's salt:  $3K_2O, 6C_2O_3, Sb_2O_3, 12H_2O$  (*Ann. Pharm.* 105, 250), with the exception of water, which amounts to only 2.57 molecules, as the following tables will show:—

	Found.	Calculated for.
Antimonious oxide ..	25.83	$Sb_2O_3$ .. 292 .. 25.51
Potass .....	23.13	$3K_2O$ .. 282 .. 24.69
Anhydrous oxalic acid ..	38.11	$6C_2O_3$ .. 432 .. 37.82
Water (loss at 150°)....	11.90	
	99.97	

#### DISCUSSION.

Mr. MELLOR said that his attention had been directed to the oxalates of antimony about six years ago, and since then more than a hundred samples had been tested in his laboratory. The first samples contained 12.5 per cent. of antimony (estimated as metal), later samples contained about 18 per cent., but now they could be bought containing 22 to 22.5 per cent. Speaking in round numbers, the percentage of antimony estimated as metal, and not as oxide,

of the three salts of antimony mentioned by the author, were antimony oxalate (first quality) 22 to 22½ per cent., tartar emetic 35 to 35½ per cent., and antimony fluoride 39 per cent. Inasmuch as it was the antimony contained in any of these salts which served to fix aniline greens and blues, the buyer had in these percentages a standard of value for the article he was using. Considerable annoyance and loss had occurred to printworks managers from the sale to them of the oxalate as true tartar emetic, and its indiscriminate use in all styles of work. He would therefore strongly urge them not to use tartar emetic substitutes in any prints or combination of patterns which involved the use of ultramarine blue, dove, or brown colours, but with all other colours the substitutes would serve with equal advantage, always provided that the percentage of antimony was equal to that contained in tartar emetic.

Mr. WALKER had found by experience that it is best not to use the oxalate to fine greens and reds in combination, but for other colours the results had been very satisfactory.

Mr. LEVINSTEIN felt that the question whether antimony oxalate could in practice replace tartar emetic, weight for weight, in fixing tannate lakes or materials containing tannic acid, notwithstanding that the tartar emetic contained nearly twice as much antimony oxide, was not alone of interest to dyers and printers, but also to English manufacturers of antimony compounds. So far as he was aware, the oxalate was not made in this country, and no doubt its manufacture would be gladly taken up if English makers could be sure of a market. Opinions were, however, divided as to its action. Noelting, and with him O. N. Witt, asserted, as they had heard, that the oxalate could fully replace the tartar emetic, not only for fixing tannate lakes, but also in uni- or single-colour dyeing. On the other hand, Hirzell holds the opposite view, and his experiments had been in some degree confirmed. Noelting tried to explain Hirzell's failure by attributing it to the use of too concentrated solutions. Clearly, then, this divergence of views pointed conclusively to the necessity for further investigation. Did equal quantities of oxalate really replace equal quantities of tartar emetic; and if so, could the former be used in all instances? According to Witt, oxide of antimony in the form of oxalate fixed tannate lakes more easily, or, in other words, the oxalate dissociated its antimony oxide more readily than tartar emetic. It was well known that in one case the residual product of decomposition was acid potassium oxalate, and in the other acid potassium tartrate. What was the action of these residuals on colours? In uni-colour dyeing, where fabrics were first impregnated with tannic acid and immersed in tartar emetic, it might be practicable to keep the latter in permanent use, unless Witt's contention, that antimony tannate dissolved more easily in acid potassium tartrate than in acid potassium oxalate, were proved to be just. Even this, however, was not conclusive, as it would be quite possible to find means to assist in the dissociation of the salt, or counterbalance the injurious action of the residual acid potassium tartrate. These points should be set at rest, and in the meantime he would urge dyers who still adhered to tin preparations, to make themselves better acquainted with the action of antimony compounds on tannic acid or sumac, by which undoubtedly more brilliant lakes were formed than by either stannate of soda or muriate of tin. It might be inferred from the author's paper that Messrs. Koepf first introduced this oxalate. This was, however, not the case, as the salt had wittingly or unwittingly been in use in England for years. To Messrs. Koepf, however, must be granted the credit

of being the first to produce and sell it under its proper name.

Dr. GROSSMAN quite agreed with Mr. Levinstein as to the importance of proving the comparative values of oxalates and tartrates, and thought that there was no one better qualified for the task than the author. Many years ago Dr. Gerland had published a volumetric method for the quantitative determination of tannin by means of tartar emetic, and had then pointed out the influence exerted by neutral salts upon the precipitation. Having regard to this influence of neutral salts on the precipitation of tannin and antimony, it seemed to him that the divergences of opinion mentioned might arise from the fact that, in the recorded experiments, various disturbing ingredients had been present, and influenced the reaction. Whatever might be the result of the discussion, he trusted that chemists would not lose sight of Dr. Gerland's quick and reliable method of estimating tannin, which hitherto had not met with the recognition which it deserved.

Mr. WATSON SMITH drew attention to the fact that in the August number of this Journal, page 493, an abstract of a paper in the *Bulletin de la Soc. Ind. de Mulhouse* (1885, 318), appeared, entitled, "The Use of Oxalate of Antimony in Printing." This paper, by E. Jacquet, contained directions for the use of antimony oxalate in printing, and these were of value as arising from the practical experience of a Mülhausen expert.

The CHAIRMAN thoroughly agreed with Mr. Levinstein in urging the necessity of further experiments to determine the efficiency and economy of the rival salts.

---

## ON THE VALUATION OF CRUDE NAPHTHAS OF COMMERCE.

BY GEORGE E. DAVIS.

CRUDE naphtha—first runnings, or the light spirit of coal tar—is the raw material from which most of the purified benzols of commerce are prepared, and as it varies very much in quality, it is generally sold by the indications yielded by some chemical test.

The method usually employed is to distil a quantity (generally 100cc.) in a tubulated glass retort, and to catch the quantity distilling over, up to a temperature of 120° C., the bulb of the thermometer being immersed the whole time in the boiling liquid. What is considered an average sample of crude naphtha should yield, on distillation, 30 per cent. at 120° C., and this is generally the basis on which this article is sold, so that contracts are usually made at so much per gallon for 30 per cent., with a rising or falling allowance per degree (or every one per cent.) within reasonable and pre-arranged limits.

Crude naphtha varies in quality according to the source of the tar from which it is distilled, and writing from the examination of a large number of samples extending over upwards of ten years, and from the results of working on the large scale, I can confidently say that the foregoing method of testing is both illusory and unsatisfactory. Sellers may prefer the test on account of its simplicity, but buyers of crude naphtha and rectifiers of benzol usually have some secret method of their own, which they employ when offering for a parcel by sample, and so are often able to avoid making a doubtful purchase. In the case of contracts it is different—if say twelve monthly deliveries have to be made, each parcel may vary

widely in its composition to the detriment of the purchaser, and yet the seller be well within the four corners of his contract.

Such a state of things needs reforming, and now that crude naphtha is practically unsaleable, this seems the time for inaugurating a change. It must not be forgotten, however, that the sellers of crude naphtha and the refiners of benzol are not always brought into contact with each other. Most of this business is in the hands of agents, who write round to sellers for samples of what they have to dispose of. These samples are tested (generally by a lad in the office) for what they will yield at 120° C., and offers are then requested from the refiners. Here then is an example of what all traders should do—buy in the cheapest market and sell in the dearest—if they can do so. The refiner would be able, in most cases, to draw his own inferences, if a sample was sent with the inquiry, but this is not always done, the test alone being sent.

In the case of no sample being sent, the purchase of a parcel of crude naphtha is a very risky thing, and can only be dealt with commercially, by allowing sufficient margin to cover the risk—this is the seller's loss. On the other hand, it is not the only quantity to be taken into consideration, as even with samples before them distillers vary exceedingly in the prices they offer for one and the same parcel. No doubt this is in a great measure due to various methods of valuation, and if the lowest value offered yield but an honest profit, the highest must be a failure. I say a failure guardedly, not inferring an absolute loss, as a rectifier may have to make future deliveries at good prices, which may warrant him offering more than his neighbour; but if he pays for his crude material more than the market price of the day at the moment of purchase, he is not a shrewd financier.

Crude naphtha is valuable only for the benzene, toluene, and solvent naphtha it contains, so that an adequate method of valuation should take them all into consideration. The distillation test to 120° C. will not differentiate these products, nor will it give any idea of what can be positively realised on the large scale. A considerable portion of the bulk, too, is often eliminated during the washing with acid and soda, and of this varying quantity the test takes no account. How can it then stand its ground?

As an average of many samples from different parts of England, the following distilling points are given:—

Sp. Gr.	100°	110°	120°	140°	170°	200°
·905	2	11	33	57	80	92

The distillation test at 120° C. could not be applied in the case of a very rich naphtha, such as that obtained from the gas in the carbonisation of coal, for

in this case there is but a small proportion of "solvent," of which the rectifier expects to get his due share.

The average test of a large number of samples of crude benzol, obtained by my process at the Hockingham Gas Works, gave the following test, showing how little "solvent" there is in it:—

Sp. Gr.	100°	110°	120°	140°	170°	200°
·890	61	83	90	96	98	99

There is another class of benzols or naphthas often requiring valuation—viz., "twice-run naphtha," which term may mean almost anything, and yield products even more various in their character than the products direct from tar. Some makers of it collect the lighter portions in one tank, and the "tailings" in another, the first, being richer, is sold by sample, the second generally goes to those who have been foolish enough to contract exclusively for the 120° C. test. The following are some distilling points of this class of naphthas:—

Sp. Gr.	100°	110°	120°	140°	170°	200°
·878	0	17	41	72	91	99
·888	3	23	46	71	88	95
·901	2	20	40	62	80	90
·901	0	9	29	57	81	95

It may be inferred, with safety, that the simple specification of so much per cent. distilling at 120° C. is no guide whatever to the amount of valuable products the rectifier can get from a parcel.

Some years since I was asked to verify the certificates of a number of deliveries of crude naphtha by means of a specified test, which, being much better than that just described, I will give in detail:—100cc. of the naphtha to be distilled in a 200cc. flask, with a thermometer arranged so that the bulb shall be just off the bottom of the flask. The distillate to be caught in a 100cc. graduated measure, and the yield at the following points taken:—100°, 110°, 120°, 140°, 170°, 200°. The quantity which shall have passed over at 140° C. is to be again distilled, and the yield at 100° C. and 120° C. noted. All which passes over up to 100° C., in the second distillation, is called *Benzol*; that which passes between 100° C. and 120° C., in the second distillation, is called *Toluol*. *Best Naphtha* ( $N_1$ ) is that which passes between 120° C. in second distillation and 170° C. in the first. *Second Naphtha* ( $N_2$ ), that caught between 170° C.—200° C. in the first distillation; and *Cresolate* (C), the difference between 100cc. and the yield at 200° C. in the first distillation.

The following are some tests, by this method, of samples which passed through my hands at that date:—

Sp. Gr.	First Distillation.						Second.		Products.				
	100°	110°	120°	140°	170°	200°	100°	120°	B	T	$N_1$	$N_2$	C
·886	2	22	12	67	88	91	23	53	23	30	35	6	6
·893	11	30	50	72	88	95	27	56	27	29	32	7	5
·903	2	11	23	56	78	92	23	42	23	19	36	11	8
·915	0	2	11	29	73	94	7	26	7	19	47	21	6
·917	2	16	31	57	75	87	22	43	22	21	32	12	13
·910	2	10	21	42	59	69	23	36	23	13	6	17	10

Now although this method appeared to suit certain buyers it seemed to me necessary to examine a large quantity of these products, and for this purpose five bottles were used to collect the different fractions from many samples. The distillation of them showed as follows:—

B	85°	90°	95°	100°	110°	120°
T	2	48	71	80	90	95
N <sub>1</sub>	130°	110°	120°	130°	135°	
	47	75	86	94	96	
N <sub>2</sub>	130°	110°	130°	160°	170°	180°
	13	43	63	79	91	93
N <sub>3</sub>	160°	170°	180°	190°	200°	
	2	31	55	74	87	

The creosote in the fifth bottle crystallised into a solid mass. The above shows clearly that the method is not exact enough for times of great depression and minimum profits, and, moreover does not indicate truly the maximum price which may be offered to the seller. The "benzol" is only of 80 per cent. quality, while the "toluol" is nearly a 50/90 benzol. The naphthas (N<sub>1</sub> and N<sub>2</sub>) are but mixtures of solvent and light oil, which have to-day very different valuation figures.

As a comparison to the foregoing, I have lately applied the method to the valuation of the crude benzol produced from coal gas, and have arrived at the following figures:—

B	85°	90°	95°	100°	105°	110°	120°
T	42	78	88	92	95	96	dry.
N <sub>1</sub>	115°	120°	130°	140°	150	160	170° 180° 190
	45	71	84	90	93	95	
N <sub>2</sub>	110°	130°	160°	170°	180°	190°	200°
	4	15	36	52	63	72	78 83 88
	4	17	30	43	56	68	78

The creosote was a completely solid and hard cake.

These tests show that although the methods usually employed may give the distiller some faint guide of the quantities to be expected from the still, they can scarcely be called scientific, and for one good reason, that they do not take into account the products eliminated during the washings with acid and soda, the loss in these operations being often very great. To take a case in point—1500 gallons of crude naphtha (for sake of identification we will call it HB) tested:—

B	T	N <sub>1</sub>	N <sub>2</sub>	C
25	23	32	10	10

This quantity, after washing with ROV and soda, measured 1200 gallons, and tested:—

B	T	N <sub>1</sub>	N <sub>2</sub>	C
26	14	21	9	27

When this quantity was worked in a still of the best construction, the yield was:—

90% benzol	318 gallons=23%
50% benzol	362 " =24%
Solvent naphtha	156 " =10%

The test would therefore lead us to suppose that

much more solvent naphtha could be obtained than was actually the case.

In another instance, 1500 gallons of crude benzol from gas of our own make, tested:—

B	T	N <sub>1</sub>	N <sub>2</sub>	C
70	6	9	4	11

After washing with R.O.V and soda it measured 1440 gallons, and tested:—

B	T	N <sub>1</sub>	N <sub>2</sub>	C
69	5	9	1	11

When worked in the still it yielded:—

90 benzol	1166 gallons=77%
Solvent naphtha	33 " =2%

Here the test indicates much nearer the yield on the large scale than with crude naphtha; but there is very little, if any, of the crude benzene from carbonising to be found in the market.

The method I have found to be of great service in the valuation of crude naphthas is as follows:—200cc. of the crude naphtha are agitated with 20cc. of concentrated oil of vitrol in a globular, stoppered separating funnel of 300cc. capacity. After agitating well for five minutes, allow to settle, and run off the acid carefully so that nothing is lost. (It is better sometimes to give two washings with R.O.V. of 10cc. each, instead of one washing with 20cc.) Now wash twice with 30cc. of water each time, running off the wash waters very carefully, then add 30cc. caustic soda solution (sp. gr. 1060) and again wash with water. Pour the washed naphtha into a measuring jar and determine the percentage loss. All is now ready for the distillation. Measure off 100cc. of the washed naphtha, less the percentage loss (thus if the loss has been 10 per cent. 90cc. will have to be taken, and so on) and place in a 200cc. flask fitted with a delicate thermometer and Glinzky's or Le Bel Henniger's fractionating tubes, connecting it with a Liebig condenser of the ordinary pattern. Heat the flask with a rose-burner, and so regulate the flame that a drop distils over about once in every two seconds. Carry the distillation on until the thermometer has risen to 120° C., catching the distillate in a graduated jar. At this point change the receiver, and catch all that comes over up to 170° C.

The distillate to 120° C. consists substantially of benzene and toluene; that portion distilling between 120° C. and 170° C. is solvent naphtha, the remainder creosote. The "solvent" produced in this small apparatus will show first drop at 125° C. and 90% at 160° C., which is usually the quality worked for on the large scale.

The composition of the distillate to 120° C. will vary somewhat with every sample of crude naphtha operated upon. In my own case, the quantities yielded by each analysis were collected from many samples, and when mixed and tested in the usual way employed for 90% and 50% benzols, showed 64% at 100° C. and 93% at 120° C., and I have found this method so handy in practice, that it is easy, without any supervision, to run the specified quantities of 90's and 50's from the still direct, without any fear of mistakes.

When operating upon "crude benzols" from coal-gas, the quality is much higher, and generally runs

Sp. Gr.		OLD METHOD.	IMPROVED METHOD.					NEW METHOD.				
		at 120° C.	B	T	N <sub>1</sub>	N <sub>2</sub>	C	Loss.	at 120° C.	Test at 100° C.	Solvent. Creosote.	
Crude Naphthas	886	42	23	30	35	6	6	13.5	50	60.	23	27
	902	31	19	22	35	15	9	18.5	46	59	19	36
	908	29	17	23	39	13	8	10.5	45	61	23	32
	924	32	30	13	27	15	15	16.5	47	58	13	40
Crude Benzols.	885	89	80	5	11	2	2	6.7	82	91	2	16
	895	77	70	6	9	4	11	7.5	77	92	2	21
	900	71	64	9	9	5	13	8.5	71	93	4	25
	909	61	55	12	10	3	10	7.0	67	91	6	27

94% at 100° and 98% at 115° C. The results of the older methods, as compared with the new, are given in table on previous page.

In order to rapidly estimate the quantity of 90%, 50%, and toluol which may be run from the still, I have constructed the following table:—

MIXTURES OF 90 BENZOL WITH 50 90 BENZOL.

90.	50 90.	First drop.	at 100° C.	at 120° C.
0	100	92	30	90

95	5	84	88	93	95	dry.
100	0	81	90	94	96	dry.

Thinking it may be interesting to have the distilling points of 90% and 50% benzol, made with pure benzene and pure toluene, I have made the following mixtures with great care, and from materials prepared as pure as it is possible to make them:—

*Pure benzene.* Collected from a large still, crystallised in the Linde ice machine, partly melted and filtered, and again rectified, collecting only the middle portion. It possessed a gravity of .884, at 15° C., distilled at 80° C. to 81° C., the thermometer falling again to 80° C. near the end of the distillation. When distilled with open steam, the whole came over at a constant temperature of 69° C. (the thermometer in the vapour), the ratio of benzene to water being 16 to 1.

*Pure toluene.* Prepared in the toluene rectifying apparatus, and re-rectified several times. It had a sp. gr. of .871 at 15° C., and distilled over at 110° 8 to 111° C. When distilled by open steam the whole came over at 84° C. (thermometer in the vapour), the proportion of toluene to water being 5 to 1.

*Pure xylene.* Prepared from solvent naphtha on the large scale, and rectified by means of Glinsky's tubes in the laboratory. It came over between 137° C. and 140° C.

The following mixtures were found to produce results as follows:—

Pure benzene	75	50
.. toluene	21	40
.. xylene	1	10
90 benzol.	50 90 benzol.	

and their distilling points for every degree, when distilled in the ordinary manner used for commercial benzols, were as set forth in the table on next page.

Now as to valuation. It is very evident that the old method based on so much per cent., distilling at 120° C., is extremely variable. When benzene, toluene, and the lighter portions of solvent naphtha are equal in price, then, and then only can the method approximate to its real value, but it *never* can be accurate, as crude naphthas

without exception, contain very large and variable percentages of light and heavy hydrocarbons which are removed by treatment with strong vitriol and soda. It is nothing more nor less than a lottery to buy by such a test.

In the second, or improved method, the valuation is simplified, but the B, T, N<sub>1</sub>, N<sub>2</sub>, and C as proved by their distillation points are not of the quality usually known in commerce, and, moreover, the same fault exists as with the old test—viz., that the test is made upon the unwashed and indefinite article. Thus there is a certain amount of risk, and this must occasion a lower price being offered to the seller to cover that risk.

° C.	90	50	° C.	90	50
87	First Drop.				
88	10		105	91	68
89	18		106	—	70
90	29		107	—	71
91	56	First Drop.	108	95	73
92	70	—	109	—	75
93	71	2	110	95½	78
94	76	11	111	—	79
95	80	22	112	—	82
96	82	29	113	96	83
97	85	34	114	—	84
98	87	43	115	—	86
99	88	46	116	—	87
100	90	59	117	97	88
101	91	55	118	—	89
102	91½	57	119	—	90
103	92½	61	120	98	91
104	93	64	..	..	..

The valuation figures will, of course, depend upon the market prices of the finished articles, though few distillers would be able, without having practically worked many parcels, to say definitely what margin should be allowed between the purchasing and selling prices of the various constituents.

In 1875, when the prices of the finished articles were as follows:—

Benzol, 90% .....	6½	f.o.b. Goole, casks free, less 2½ cash in 14 days.
Toluol 50% .....	5½	
Solvent (N <sub>1</sub> ) .....	2½	
" (N <sub>2</sub> ) .....	1½	

The values for the analytical products were as follow:—

B.	T.	N.	N <sub>2</sub>	C.
1/7	2/6	1/6	1/1	1d.

So that a crude naphtha, such as that alluded to as H B, and worked in the still, would have been worth:—

B	25 × 48d. = 1200
T	23 × 30d. = 690
N <sub>1</sub>	32 × 18d. = 576
N <sub>2</sub>	10 × 12d. = 120
C	10 × 1d. = 10
	2396
	100
	= 2/2 per gallon.

To-day the selling prices are—

90%	50%	Toluol	Solvent	Creosote
1/7	1/4	1/2	10d.	no value

and the values of the analytical products:—

Bd.	Td.	N <sub>1</sub> 6d.	N <sub>2</sub> 1d.	C nil
-----	-----	--------------------	--------------------	-------

making the value of such a crude naphtha to-day, by this method, but 6½d. per gallon.

The figures obtained by my method are absolute and comparable, from whatever part of the country the crude material is derived, the percentage loss, and the heating which takes place on treating with acid gives one a very good idea of the quality of the stuff one has to work, while the distillates represent very faithfully the quantities of benzol and solvent naphtha to be obtained on the large scale. Take, for instance, the H B sample again—by the new test it gave:—

Loss by washing .....	18½
Distillate to 120° C. ....	15
Test of same .....	100
Test of same .....	71
Distillate to 170° C. ....	126
Test of same .....	100
	0
	92

The quantities actually obtained from the still were:—

90% benzol .....	23½
50% .....	24
Solvent .....	104½
Test of solvent .....	130
	1
	91

Loss by washing 20½

Knowing this, it would be easy to make an offer for any parcel, with the certainty of knowing that the laboratory results will be produced on the large scale, and the test may be made one in which both buyer and seller could agree upon a sliding scale, the price f.o.b. Goole, or d d in London, being made the basis. Of course, the percentage of the selling prices each manufacturer could afford to give would vary according to circumstances. One with a good pattern of still and a careful rectifier working it, would be able to offer more than one using an old boiler for a still, and injecting steam *ad lib.* into the contents. One may have cheap vitriol for washing, cheap labour, or cheap carriage, which another would not possess, and all these things would have to be taken into consideration.

A rectifier of crude naphthas should be able to say, "I know by the test what I am able to get out of the parcel, and will offer so much per cent. of the selling price, calculated naked at my works, for the 90's, 50's, and solvent contained therein;" the seller delivering the naphtha to the purchaser's works free, the barrels to be returned free when empty. Some manufacturers are able to do this; it is for sellers to know it can be done in a satisfactory manner. Now, taking this selfsame crude naphtha again, let us see what money values were obtained from it.

90% benzol .....	23gals. at 1/7	f.o.b. Goole casks free, less 2½ cash in 14 days.
50% .....	24 " at 1/4	
Solvent .....	10 " at 9d.	

But we must deduct 2d. per gallon for barrels, 2d. for carriage, and 1d. for sundry charges, as leakages, super tares, etc., leaving naked at the works:—

90% benzol .....	23gals. at 1/2 = 322	d.
50% .....	24 " at 11d. = 264	
Solvent .....	10 " at 1d. = 40	
	626	
	100	= 6½ per gallon.

Out of which the rectifier will have to find vitriol, soda or lime, wages, steam, repairs, depreciation and other sundry charges, and his profit if there be one.

The present state of things is most unsatisfactory, both for buyer and seller, and if this paper tends to bring about a better state of things it will not have been written in vain.

## NOTE ON THE COMPOSITION OF GAS FROM MESSRS. ALLHUSEN'S BORINGS AT MIDDLESBROUGH.

BY PROFESSOR P. PHILLIPS BEDSON, D.Sc.

THE two samples of gas, the composition of which forms the subject of this short note, were collected from two distinct outbursts of gas which occurred last July during the piercing of the salt at the second of Messrs. Allhusen's borings at Middlesbrough. A similar outburst of gas took place during the piercing of the salt at the first of the borings, the gas issuing from the bore hole in large volumes, shooting into the air, water, mud and debris, to a height of several feet.

For the opportunity of examining these gases and for their collection I am indebted to the kindness of Mr. A. Allhusen.

The gas was collected by placing in the bore hole, at the time of the outburst, an iron tube some 6ft. in length and about 2in. in diameter. This tube was connected by indiarubber tubing with a large glass vessel, such as is used in the construction of aspirators, filled with water. The iron tube was connected with the upper opening of the aspirator, and, by allowing the water to flow out, the gas was drawn in.

The salt was reached at a depth of about 1000ft., and after it had been pierced to a depth of some 82ft., the first outburst of gas occurred. The gas collected proved to have the following volumetric composition:—

Oxygen .....	1.53
Marsh gas .....	1.90
Nitrogen .....	96.57
	100.00

The second outburst occurred at a depth of 106ft., the collected gas having the following volumetric composition:—

Carbon dioxide .....	0.3
Oxygen .....	2.9
Nitrogen .....	96.8
	100.0

From Mr. Hugh Bell's paper, "On the Salt Deposits of Middlesbrough," read before the Cleveland Institution of Engineers in April, 1883, it will be seen that the salt of these deposits contain vesicles, locked up in which is gas, the liberation of which, on the solution of the salt, is frequently productive of slight explosions. This gas is said to consist of nitrogen and oxygen, in the proportion of 91vols. of the former and 6vols. of the latter. The Middlesbrough salt, therefore, resembles certain

varieties formed in the Wieliczka deposits, which exhibit similar decrepitations; the gas contained in them being, however, marsh gas only. Further, Mr. Bell mentions in his paper that, during the stoppage of the pumping at Clarence, large volumes of gas bubbled up at the fresh-water inlet of the pumping machinery. This gas proved to contain 97.9vols. of nitrogen and 2.1vols. of marsh gas. Now supposing the oxygen in the gas obtained at the first outburst, to represent air admitted in collecting the gas, the residual gas would contain the following proportions of marsh gas and nitrogen:—

Marsh gas .....	2.05
Nitrogen .....	97.95
	100.00

Showing it to be identical in composition with that described by Mr. Bell. If the results of the analysis of the gas obtained at the depth of 106ft., be interpreted in a similar manner, the residual gas would have the following volumetric composition:—

Carbon dioxide .....	0.4
Nitrogen .....	99.6
	100.0

## CHAIRMAN'S OPENING ADDRESS.

MR. J. NEILSON CUTHBERTSON said: It has appeared to me, in considering the many subjects that present themselves as suitable for an address, that, in my capacity as a member of the School Board, I might most appropriately refer to the present position of scientific and technical education for the masses of the people. You are probably all aware that four years ago a Royal Commission was issued to inquire into the instruction of the industrial classes in technical and other subjects, with power to take evidence and visit foreign countries. The report of the Royal Commission has been in the hands of the public for more than a year; I have no doubt you have a copy of it in your library, and it must be known to many of you. But, believing the subject to be of such importance that too much attention cannot be given to it, I venture to direct some thoughts to the conclusions of that report. The Commissioners say that they have visited almost every country in Europe, and also in the United States of America; and although they had high expectations of what

they should find there, their expectations were exceeded, and there is no doubt, they say, that many and great advances have taken place in Continental nations in the matter of technical and scientific education. I need only refer you to the most recent development of that education in the splendid university which has been erected at Strasburg. I suppose this new university is expected to take a leading place amongst the universities of Europe. Probably no other university can equal it, with its ninety-two professors, its large number of students, and immense appliances in the way of apparatus and library. We can only hope that that university will have a future in keeping with the splendid preparations that have been made for its success. I might refer, as the Commissioners do, to the great success that has attended Continental science in different ways: in organic chemistry, in the introduction of the ammonia process in the alkali trade, in the ventilation of deep mines, in the application of water power, in the invention of the dynamo machine, in the construction of roofs and bridges, in the printed cottons of Mulhouse, in the woollen yarns of Verviers and in the ribbon trade of Basle. All this is largely due to the greater painstaking, to the greater pliancy and thrift of those concerned, and also to the general acquaintance with modern languages usually possessed by Continental manufacturers.

The reporters go on to say that notwithstanding the great advance that has taken place in these foreign nations, on the whole our people still maintain their position at the head of the industrial world. You must all have been struck with the recent addresses of Sir Lyon Playfair at Aberdeen and Dundee, and how completely he places foreign nations ahead of our own in this matter of scientific education. I am inclined to believe, however—and this report bears me out—that we are not so far behind after all. I think Sir Lyon's words may be taken to mean that we are all right up to a certain point, but require to take care of our hand in time to come. In proof of this position the Commissioners cite the important inventions that have been brought out in this country during the present and the past generations; in fact, they go the length of saying that all the principal machinery that is now at work on the Continent has been derived from England, or, at all events, is the direct offspring of suggestions made in Great Britain. Even in those branches where other nations have hitherto excelled, the reporters are of opinion that we are improving. They maintain—and I hold correctly—that the beginnings of the modern industrial systems are due in the main to Great Britain. Other nations were greatly hindered during the latter part of the eighteenth and the beginning of the nineteenth century by the wars which devastated Continental Europe, and so jealous was the nation at that period and at the close of the great war, that legislative restrictions were imposed which hindered our people from going abroad, and even put a hindrance in the way of exporting machinery to Continental countries.

This was no doubt the occasion of the great efforts put forth by Continental nations to cope with this country, and they began by instituting Polytechnic Schools. These schools are all over the Continent. There is *L'Ecole Centrale* at Paris, and there are the Polytechnic Schools of Germany and Switzerland; and the first step they took was to get men from England and Scotland to start them. After that sprang up the Technical High Schools, for a lower grade of instruction, inaugurated in most of the Continental States. These two grades of schools have been kept mostly at the expense of the different States—I mean the Governments. The result is that every one who has had to do with Continental manufacturers

must have noticed the greater intelligence of their chief men. A Continental manufacturer is generally a man of education himself, and thoroughly up to all the new inventions of the day. He is generally acquainted with several languages, and has thereby the opportunity of studying the periodicals of this country and the literature of the day all over Europe, and of picking out the inventions and appliances most suitable for his own trade. More recently there have been instituted in many of the States Technical or "Industrie-Schulen," intended for boys and young men who wish to become foremen, or otherwise engaged in industrial occupations. The instruction in these schools is similar in character to that of the higher instruction, but inferior in degree. In France they have taken a very large development and are generally treated as higher elementary schools, to which the cleverer boys are passed on after they have completed the curriculum in the ordinary schools. This idea of picking out the cleverer boys is common to the schools in America as well as to those of Continental Europe. They don't bring on the dunces to the higher schools; they examine each scholar after the curriculum has been gone through, and if he can't pass a creditable examination, he is not passed on to the higher school unless at his own expense. Notwithstanding all these efforts, the reporters say that foremen and workmen are not, as a rule, up to the present time, technically instructed, and that they have not—even with all the efforts that have been made—greater advantages than our workmen or foremen have in this country. This class of effort has been chiefly maintained by local effort, and largely by the manufacturers themselves, who seem to be quite aware of the necessity nowadays of scientific instruction, even amongst their men, at all events amongst their foremen, and they spare no pains to have them educated. Nothing, however, that they have yet been able to achieve is equal to the instruction that we have in this country through the schemes of the Science and Art Department and the City and Guilds of London Institute.

In two respects scientific education abroad seems to excel what we have at home. First, as regards *drawing*; and second, as regards *general elementary education*. In France and Belgium an effort is made to have every child instructed in drawing; and in regard to the United States, the Commissioners consider the great feature of technical instruction there is the superior general education, which the mass of the community receive in the elementary schools.

I need not say that this latter deficit will not much longer exist, for I maintain that the mass of our people, by another generation at all events, will be as well, if not better educated than their American cousins.

Now, to bring home these remarks to our own country, the reporters wish to point out the need we have of technical instruction, especially for foremen and artisans. The time was when it was supposed that instruction of that kind had better be reserved for the head of the house, with one or two assistants in the laboratory, but I hope that day is at an end. We have now our mechanics' institutions blossoming into colleges of science and arts. We have evening classes everywhere for science of a kind. I don't pretend for a moment that the science thus to be had is of the very highest level; at all events it goes so far as to accustom young people to elementary ideas regarding science, and to bring out (which I think is a great point) those who have the aptitude and abilities for following out the higher studies. In proof of this, I may cite the opinion of a gentleman well known to you all, who was called upon to examine a school in elementary science. I said to

him, "Now, do you think that what you have seen there is likely to interfere with your own professional work?" "Not at all," he said; "I believe that all that anyone can do in that direction will only be a feeder to the higher institutions." I think if this view be taken, you will find in future a much larger number of boys who would be desirous to have higher scientific instruction. They point also to the examples of special schools. I am not acquainted with the lace trade in Nottingham, but from the report it seems that Nottingham has been largely benefited by an art school there, and the lace trade which had been languishing has got a new impetus; and it is known to us that the Lambeth School of Art has been the means of raising the Doulton pottery to a higher position than it might otherwise have attained. I need scarcely mention to you, gentlemen, the City and Guilds of London Institute. There we have an effort put forth by the Guilds of London, who are possessed of immense wealth, and who of late years have been looking about to make a good use of it, lest it should be taken from them in another way; and we must certainly approve of what they have been doing. All over the country they hold examinations which have been the means of bringing forward a continually increasing number of candidates. Their rewards are of a very substantial kind, including medals and money rewards; and I have no doubt many working men have been brought out who otherwise would have remained unnoticed. The universities, too—to ascend to a higher platform—now give a much larger medium of natural science than formerly, and I am quite sure professors of science in universities will cordially welcome any movement in that direction. Indeed, I may say that throughout the whole community there is a growing desire, and especially amongst educational bodies to promote scientific and technical education; and a desire, above all things, to know how it can be best accomplished.

The reporters are of opinion—and I dare say we all agree with them—that the foreign systems are not exactly applicable to this country. There is a kind of autocratic fragrance about them, that could not rightly be transplanted into British soil, and we must look at home for something of a more natural and easy growth. With the exception of France, where the recent educational revival has assumed enormous proportions, the British Government is now spending a larger sum of money than any Government in Europe upon its education, and all that is needed is to see that it be properly and wisely dispensed.

In a general way it may be taken for granted that men of leisure and means have no difficulty in this country in getting scientific education. I may perhaps differ with Sir Lyon Playfair as to this point, for, as far as I remember, in Glasgow there never has been a time that there was not good scientific education. In fact, I have been often astonished to hear people from a distance speak of the difficulty of getting instruction in chemistry. In all my recollection there have always been schools of chemistry in Glasgow, still increasing in usefulness and popularity, so that people of very moderate means have hitherto had no difficulty in getting scientific education. The best preparation, the Commissioners remark, for studies of that kind, is a good system of secondary schools, and they point above all others to the Manchester Grammar School, as a school which has of late years been brought up to a high point of efficiency, and which they recommend as an example to others. I hope that in Glasgow we shall be able, with the assistance of the Endowments Commission and of other local authorities, to have abundance of scientific instruction of that higher grade. But that

is not quite the point at which the Technical Commission has been aiming. It is rather how are the great mass of the working population to be instructed in elementary science. There can be no doubt that that ought to be begun in the primary schools. The Commissioners consider that if general ideas of science be given to children of ten, eleven, or twelve years of age (as I stated at the earlier part of my remarks), this will prove to be seed sown in the minds of boys, which will bear fruit in the form of a hunger for greater information; and they think this should be done by special teachers, or by visiting masters, as has been done in Liverpool and Birmingham—going round the schools on certain days of the week giving lessons in elementary science—and then the scholars so initiated should be led up to higher schools or classes, either day or evening. This sort of work involves a set of apparatus, which, of course, must be supplied from some public source. They seem to think that the School Boards would not be able to overtake that, but I have yet to learn that the Scotch Act of 1872 does not include this to such moderate extent as may be required. They also recommend the institution of industrial museums and loan collections, and that all these should be largely promoted by employers and manufacturers. There is no doubt, as I have already said, that what is being done in that connection on the Continent is promoted by employers of labour more than by the Government; and I feel quite sure that great employers of labour in this neighbourhood need only to have their attention called to this matter to be willing to encourage such scientific education among the people whom they employ. It is also recommended that manual work should be introduced into the public schools. Regarding this there may be differences of opinion. It has been done very successfully in Allan Glen's School, in the City of Glasgow, and in the Buchanan Institution, and in some towns in England. The reporters give a list of all the different institutions and colleges they have visited, and while not willing to differentiate between one and another, they are anxious to believe that all are doing good work, and only require greater encouragement and greater support in the way of funds, to do a much better work. They make again and again reference to the technical examinations of the City and Guilds of London Institute. I know scientific men are apt to pool-pool this sort of thing, but what I say is that in the absence of anything better we are very glad to have it, and if it be but the beginning of a better state of things we shall have good cause to thank them and to hope that they may continue to prosecute their labours.

At the close of their report the Commissioners make one or two suggestions. In the first place they suggest that in the public schools drawing should be incorporated as a class subject. Drawing does not so much concern us as a society, but still it seems to be applicable to most branches of scientific study, and one good effect the publication of this report has had is, that now the Education Department have issued instructions that drawing shall be taught to every child—boy and girl—and no doubt this will result in much good. They express their own opinion that boys especially should be taught to use tools in wood and iron, and that this should be made a "specific subject" in the education code. They also suggest that the provision which is now operative in Scotland, to prevent a boy or girl under 14 years of age from being employed full time, unless they have passed the fifth standard, should be extended to England. As to classes in connection with the science and art department they consider that the local authorities, school boards, or others,

in the department where the scale is frozen and pressed. I am very glad that Mr. Beilby has not only introduced it, but succeeded in making it pay. The increase of  $2\frac{1}{2}$  per cent. must be chiefly in soft scale. Paraffin of this kind would have been, years ago, exceedingly valuable to the late Dr. Stenhouse, with whom I was associated in his early experiments on the waterproofing of cloth. At that time we required a paraffin of extreme qualities, some very hard and some very soft. Paraffin similar to this specimen would have suited us admirably, and would have made a capital waterproofing agent. As we had not paraffin of this description we were obliged to take hard paraffin and mix it with olive oil, so that when the waterproofing agent was introduced into the tissue—for example, boot leather—the crystals of scale would not produce friction. It struck me that this particular paraffin, this new soft scale, would have been the very thing for waterproofing cloth, inasmuch as it would yield to every movement of the wearer. I am sure this contribution to the technology of the subject is one of material interest and importance, and I hope Mr. Beilby will succeed in increasing the sale of soft scale.

## HIGH TEMPERATURE THERMOMETERS.

BY JAMES MURRIE.

SINCE reading the paper on a new series of thermometers before this section of the Society last session, a few modifications have been made for the purpose of indicating very high temperatures, a description of which may prove interesting.

The principles embodied in the construction of the apparatus have been already explained (*Journal*, iv. 45, 189). The essential feature consists in the raising of the boiling point of a liquid by pressure, the liquid being confined in an expansion chamber, which forms one end of a hollow tube, the opposite end of the hollow tube being practically sealed by means of a pressure indicator. On taking indications of temperature, the expansion chamber is subjected to the action of the heat: the confined fluid in consequence expands, and in the act of expanding tends to compress the liquids placed in the hollow stem intermediate to the expansion chamber and the pressure indicator; the indicator being graduated to show the corresponding temperature.

For indicating low temperatures, a fluid of comparative volatility may be employed. For temperature above  $400^{\circ}$  Fahr., mercury has been found suitable, the upward limit of an instrument for continuously indicating the temperatures being  $1700^{\circ}$  Fahr. Above this point the metal becomes too plastic and porous to contain the vapour.

For continuously indicating temperatures above  $1700^{\circ}$  Fahr., the apparatus is not adapted, although it can be modified to enable indications being taken at intervals, the maximum range being about  $4000^{\circ}$  Fahr. The expansion chamber is enveloped in a conducting body, and attached to, or forming part of, the indicator is a time recorder. On the expansion chamber with its coating being brought in contact with the heating body, the mercury in the expansion chamber is slowly heated, depending more particularly on the intensity of the heat surrounding said casing. The indicator registers the degree of heat, and a chronograph records the time taken to raise the temperature of the mercury between two predetermined points. It is, of course, necessary to withdraw the instrument from the action of the heat before

the temperature of the mercury is sufficiently raised to create a pressure which would destroy the instrument.

For very high temperatures, more particularly when the heated body is in a gaseous form, the difficulty is in obtaining a sufficient volume of gas at a nearly uniform temperature. Above  $3000^{\circ}$  Fahr., the temperature is rarely constant for any period at a fixed point, and in consequence the indications obtained by means of the apparatus cannot be taken at the maximum temperature existing in the furnace or oven. When the heated body is in a liquid form, and the chamber completely immersed in the metal, the temperature can be better determined.

For temperatures under  $1700^{\circ}$  F., the main difficulty experienced has been in preventing leakage of the confined fluids, a very slight leakage having the effect of emptying the chambers of their contents.

This difficulty, however, might possibly be lessened, if not overcome, with the result that the duration of immersion would not materially affect the accuracy of the register of temperature. In stating this I understand that a London scientist has given expression to different views from those I have embodied; but I have seen nothing to shake my convictions as to the accuracy of my conclusions in the matter.

In answer to various questions, Mr. MURRIE said:

The only liquefied gas which has been tried in the thermometer is liquid carbonic anhydride. It is at present very difficult to reduce hydrogen, nitrogen and other gases, to the liquid state; but I am at present engaged in a new process for liquefying gases rapidly and with facility, which at present I am not at liberty to describe. In the case where liquefied gases are employed, the inner chamber is, by means of a tube with a stop cock, connected with a generator in which the gas is liquefied, and from which the chamber is charged. The highest temperature at which these liquefied gases can be used depends on the pressure of the saturated vapour. Some of these vapours have so great a pressure at ordinary temperatures that it would be impossible to retain them in such an apparatus; but liquefied carbonic anhydride, for example, could be kept in the thermometer, say, to the temperature of boiling water. To take the temperature of a small blast furnace, it would have to be so constructed that the chamber of the thermometer, when inserted, would be surrounded by some comparatively non-conducting material. Thus, the mercury chamber would be surrounded with clay, through which heat passes very slowly. The mercury becomes heated at a corresponding rate, and the time taken to heat the mercury, say, to  $1500^{\circ}$  F., is noted on a chronometer, and the temperature calculated from this.

## ON THE ANALYSIS OF GAS COAL.

BY LEWIS T. WRIGHT, F.C.S., ASSOC. MEMB. I.C.E.

Coal analysis as understood by a gas-maker refers principally to two important factors—viz., the volume of gas a coal is capable of producing, and its luminosity under the conditions of his manufacture. Of course there are several other points, such as quantity and quality of coke, tar and ammoniacal liquor, sulphur, ash, etc., which must engage his attention; but the first question he naturally asks in reference to a new coal is, What quantity of gas will it produce, and of what candle-power? A correct knowledge of the capabilities of a coal is of double importance to us as gas manufacturers. In the first place we can assign to it a pecuniary value, and in the second place we are, by a knowledge of the various coals we employ, enabled to better supervise and control our operations, and determine our manufacturing losses—if any.

In the present paper I propose to consider the various methods of analysis, and, to some extent, by comparison, to discuss their relative merits, and finally to compare the results of the most approved method with actual manufacturing experience.

For the examination of a coal from a gas-maker's particular point of view, there are several means—(1.) To make a proximate analysis, and thereby discover how much moisture, volatile matter, coke, ash, and sulphur the coal contains. (2.) To make a practical analysis of the coal by distilling it (a) either in a small iron retort with other necessary apparatus for collecting the gas and measuring its volume, etc.; or (b) in a setting of clay retorts as used in modern gas manufacture, with other necessary plant for exhausting, condensing, scrubbing, purifying, measuring the gas, and collecting and measuring the liquid products and coke, just on the same lines as we operate in gas manufacture. There is another method—viz., elementary analysis, perhaps of more interest to a chemist than to practical people, but which should not be neglected if a complete knowledge of the coal is required.

*Elementary Analysis* I will not enter into, as it is fully treated on in the best text books, such as Fresenius', etc., but merely mention that the oxidising material preferred is lead chromate.

*Proximate Analysis.*—Proximate analysis may be said to consist of the following determinations:—Moisture lost at some given temperature; volatile matter; fixed carbon; ash; sulphur.

The first determination is that of moisture, and at once plunges us into doubt. At what temperature shall the sample be dried? It being known that coal does not lose all its moisture at 100° C., some recommend drying at higher temperatures than that of boiling water. Hinrichs says, put down as moisture the loss in weight of finely-pulverised coal after drying for one hour at a temperature between 105° and 110° C. Fresenius recommends 110° C.; but coal dried at 110° C. will lose more water if further dried at 150° C., and so on. So it does not appear that a temperature of 110° C. has any special recommendation in respect of obtaining all the moisture. Since 100° C. is a temperature easily secured and maintained constant by means of a water-bath, I have adopted it as a standard.

The usually adopted rule of estimating moisture by loss of weight in drying at a given temperature,

is to proceed with the drying until the weight of the substance becomes constant. This procedure is not free from error. In the first place, the loss of weight by drying at about 100° C. for any given time does not equal the actual amount of water evolved. In the second place, if most samples of coal be examined by the drying method of weighing at certain intervals of time, it will be found that after a time the samples not only cease to lose weight, but actually gain. This gain has been noticed by different observers. Hinrichs attributes the increase to the slow oxidation of some matters in the coal (pyrites, etc.); but this is a subject deserving of independent investigation, and will perhaps be found to be due to the absorption of gases into the pores of the coals left vacant by the expelled moisture. It is reasonable to suppose that the increase of weight which only exhibits itself after a large portion of the moisture has been got rid of, has really been taking place during the whole period of the drying process. In that case the water actually lost will be more than is shown by loss in weight, and this I have always found. Some experiments with coals of different character will exhibit this:—

Scotch splint, finely powdered, dried 14 hours in an atmosphere of coal gas—	
Moisture lost at 160° C., weighed as water in a drying-tube .....	(a) 10.22 per cent.
Moisture estimated by loss of weight in drying the coal at 100° C. ....	(b) 9.66 "
Another experiment given for the two methods .....	(a) 10.31 "
	(b) 9.76 "
Durham gas-coal .....	(a) 1.79 "
	(b) 1.59 "
Welsh cannel .....	(a) 4.74 "
	(b) 4.26 "

The difference between the two methods may be taken to represent the increase in weight during the drying process, and may be tabulated as follows:—

Scotch splint, first experiment .....	0.56 per cent.
Do., do., second experiment .....	0.55 "
Welsh cannel .....	0.38 "
Durham gas-coal .....	0.20 "

From which it might be concluded that the increase in weight varies in some direct proportion with the moisture.

It will therefore be seen that the ordinary method of determining the moisture in coal by loss of weight in drying is not satisfactory, and that where accuracy is required, the water must be actually weighed as such. In any case I would suggest 100° C. as the drying temperature. The determination of volatile matter will be found even less satisfactory than the foregoing determination, until some standard method, however arbitrary it may be, has been adopted by all operators. Professor Hinrichs states that the total volatile matter of coal is determined with accuracy (1 milligram on 1 grm. of coal) by taking 1 to 2 grm. of undried pulverised coal, heating for 3½ minutes over a Bunsen burner (bright red heat), and then immediately, without cooling, for the same length of time over a blast gas-lamp (white heat); and he has published some experiments in support of his conclusion, from which the following series is quoted:—

Weight of Coal.	Volatile Matter. Per cent.	Deviation.
1.910 grm. ....	49.58	-0.19
1.147 " .....	49.87	+0.11
1.051 " .....	49.85	+0.09
Average .....	49.76	
Greatest difference .....		0.29

Adopting the above method of Hinrichs, I obtained, by exercising extreme care, the following

results with two different samples of undried powdered coal—

#### DEAN'S PRIMROSE GAS-COAL.

(This coal has been exposed to the atmosphere in a finely powdered state for two years.)

Weight of Coal.	Volatile Matter. Per Cent.	Deviation.
2.018 grm. ....	31.22	-0.28
2.014 " ....	31.62	-0.12
2.009 " ....	31.66	+0.16

Average ..... 31.50  
Greatest difference ..... 0.14

#### SILKSTONE GAS-COAL.

Weight of Coal.	Volatile Matter. Per Cent.	Deviation.
2.030 grm. ....	41.57	+0.28
2.022 " ....	40.80	-0.79
2.005 " ....	41.39	+0.10

Average ..... 41.29  
Greatest difference ..... 0.67

The above experiments are not selected, but were consecutive, and though not so promising as those published by Hinrichs, they are fairly comparable.

The following experiments were made by myself. The method of operation was to weigh the coal in a thin platinum crucible without the cover, which was only used during the heating and cooling in the desiccator. The reason for not weighing the cover was that it becomes coated on the inside with a thick deposit of soot, which clearly belongs to the volatile matter. The inside of the crucible also acquires a thin carbonaceous deposit (in some of the experiments allowed for); but the error due to this deposit is small compared with those due to different systems of heating. However, it always tends to make the volatile matter too low. In these experiments volatile matter includes all moisture.

1. Experiments with Scotch splint coal (moisture 10.26 per cent.). Gas flame 600mm. long, 100mm. diameter; coal in small lumps; flame applied until all appearances of gases ceased issuing from under lid of crucible:—

Weight of Coal.	Volatile Matter. Per Cent.	Deviation.
4.768 grm. ....	41.69	-1.11
4.583 " ....	43.16	-0.36
4.472 " ....	43.96	+1.16
3.911 " ....	42.10	-0.40

Average ..... 42.80  
Greatest difference ..... 2.27

2. Coal finally powdered, all other conditions as in above series:—

Weight of Coal.	Carbon Deposit on Crucible.	Volatile Matter. Per Cent.	Volatile Matter corrected for Carbon. Per Cent.	Time. in. s.
1.110 grm. ....	0.008	43.25	43.60	1 30
1.551 " ....	—	41.61	—	1 45
2.672 " ....	0.004	43.43	43.61	2 35
3.600 " ....	—	43.27	43.55	3 30
3.878 " ....	—	42.13	—	3 45
4.339 " ....	—	42.70	42.80	4 30

Average ..... 43.24  
Greatest difference ..... 2.45

This method of heating till all appearances of gases cease issuing from the crucible, has not been found satisfactory. The experiments with powdered coal appear least so; but against this view might be urged the greater difference in the weights of coal taken for each experiment.

3. Welsh cannel (moisture 4.74 per cent.). Gas-flame as before, but heating continued for a constant period of 90 seconds:—

Weight of Coal.	Volatile Matter. Per Cent.	Deviation.
2.005 grm. ....	49.17	+0.39
2.080 " ....	48.79	-0.01
2.072 " ....	48.26	-0.32
2.024 " ....	48.91	+0.13

Average ..... 48.78  
Greatest difference ..... 0.91

4. Silkstone gas coal (moisture 7.75 per cent.). Same conditions as in series No. 2, with the exception of varying power of gas-flame:—

Volatile Matter. Per Cent.	Length of Gas-flame. 600mm.
41.33	300 "
40.23	300 "
39.56	200 "
39.18	100 "

These experiments show fairly well the differences due to the power of the gas-flame.

5. A method was tried of heating until the gases ceased, and then heating for a further period of 1 minute. Gas-flame 600mm. long, 100mm. diameter; coal powdered:—

Weight of Coal.	Volatile Matter. Per Cent.	Deviation.	Time Gases Ceased. in. s.	Total Time. in. s.
1.157 grm. ....	40.69	+0.04	1 0	2 0
1.163 " ....	40.53	-0.12	1 15	2 15
3.112 " ....	40.70	+0.05	2 30	3 20
4.150 " ....	40.70	+0.05	3 20	4 20

Average ..... 40.65  
Greatest difference ..... 0.17

These results were thought to be sufficiently good, and the method was afterwards tried with various samples of coal.

6. Dean's primrose gas coal (fresh). Conditions the same as in series No. 5:—

Weight of Coal.	Volatile Matter. Per Cent.	Deviation.	Time Gases Ceased. in. s.	Total Time. in. s.
2.021 grm. ....	33.59	+0.01	1 40	2 40
2.066 " ....	33.54	-0.05	1 50	2 50
2.130 " ....	33.66	+0.06	1 55	2 55

Average ..... 33.60  
Greatest difference ..... 0.12

7. The same powdered sample of coal was tried after two years' exposure to air. Gas-flame 600mm. long, 100mm. diameter:—

Weight of Coal.	Volatile Matter. Per Cent.	Deviation.	Time Gases Ceased. in. s.	Total Time. in. s.
(1) 2.030 grm. ....	30.88	+0.02	2 10	2 40
(2) 2.113 " ....	31.04	+0.18	2 15	2 50
(3) 2.005 " ....	30.67	-0.19	2 40	3 20

Average ..... 30.86  
Greatest difference ..... 0.37

The time required to expel the gases in these three experiments discloses an apparent anomaly which requires explanation. In all experiments it had been the practice to maintain the coal-dust as an even layer on the bottom of the crucible, and to keep the crucible in an upright position during the heating. The ring which was used in this series (7) being small, caused the crucible to cant over, and shifted the coal-dust into a little heap in the corner. This heap being thicker in the centre than it would have been if spread evenly over the bottom of the crucible, was less favourably disposed for quick heating. This explanation of the apparent anomaly was verified by an examination of the coke residue. Trifling as this point may appear, it should have attention in accurate experiments.

- 8 West Levenson coal. Same conditions as in No. 6:—

Weight of Coal.	Volatile Matter. Per Cent.	Time Gases Ceased. in. s.	Total Time. in. s.
2.081 grm. ....	32.39	1 50	2 50
2.113 " ....	32.18	2 10	3 10

Average ..... 32.28  
Difference ..... 0.21

9. Levenson coal. Same conditions as in No. 8:—

Weight of Coal.	Volatile Matter. Per Cent.	Time Gases Ceased. in. s.	Total Time. in. s.
2.153 grm. ....	33.12	1 55	2 55
2.065 " ....	33.02	1 50	2 50

Average ..... 33.07  
Difference ..... 0.1

## 10. Felling Main coal. Same conditions as in No. 8:—

Weight of Coal.	Volatile Matter. Per Cent.	Time Gases ceased. m. s.	Total Time. m. s.
2.205gms. ....	32.88	2 0	3 0
2.211 .. ..	31.80	2 0	3 0
Average .....	32.34		
Difference .....	1.08		

## 11. Australian shale. Same conditions as in No. 8:—

Weight of Coal.	Volatile Matter. Per Cent.	Time Gases ceased. m. s.	Total Time. m. s.
2.009gms. ....	78.69	1 20	2 20
2.017 .. ..	78.58	1 25	2 25
2.019 .. ..	78.55	1 26	2 26
Average .....	78.61		
Greatest Difference .....	0.14		

Series 5, 6, 8, 9, 10, and 11 were all conducted in the same manner, and with the exception of No. 10 were very satisfactory. For want of a better method I have adopted the following:—Take about 2grm. of finely pulverised coal, and let it form an even layer on the bottom of a thin platinum crucible. Weigh without cover, place the crucible (with cover on) in an upright position on an iron ring, round which has been wound sufficient platinum wire to prevent contact between the iron and the platinum crucible. Then apply a powerful gas-flame (to secure even results endeavour to keep the same length of flame in all experiments). Note when the gases cease issuing from under the lid: allow one minute further heating; remove the gas-flame, place the crucible and cover in a desiccator for about five minutes to cool, and then weigh without cover as soon as possible.

It is extremely difficult to get fair samples of cannel coal, there often being several layers within a few inches of widely different quality. The following case is quoted:—A piece of curly cannel was taken, 6 inches deep, and on examination it was found that it consisted of various thin layers without any very sharp definition, but gradually merging together. The different appearances of the layers and the volatile matter are as follows:—

Very bright black curly .....	78.8 per cent.
Shiny curly .....	76.0 ..
Dull curly .....	76.3 ..
Smooth .....	69.5 ..
.....	61.7 ..

The determination of ash is one that admits of great accuracy, if performed with due care. The very common mode of operating in platinum boats or dishes, placed on an open flame, is subject to a serious error, due to draughts carrying away some of the very fine and light particles of ash. Cannel and easily incinerated coals may be treated in a deep platinum crucible; but very refractory coals and such substances as gas carbon require a different method.

Weigh about 2grm. of the coal or coke in a piece of platinum foil, rolled so as to admit of its easy passage into a piece of combustion-tubing of about lin. diameter, and heat to redness, whilst a very gentle current of air is being drawn through the combustion-tube by means of an aspirator. Working in this way, a beautifully clean ash can be obtained in a very short time; but it is necessary to guard against using a heat that would cause the foil to fuse to the glass. It is well to know that coke absorbs moisture very rapidly. For this reason it is best to take a separate portion of coal for the ash determinations, and not to weigh a portion of the coke obtained in the volatile matter determination. The ash should be saved for the further determination of the sulphuric acid therein.

For the determination of total sulphur there have been suggested innumerable methods, such as fusion with alkali and alkaline carbonates and nitre; boiling

with hydrochloric or nitric acid and chlorate of potash; aqua regia; fuming nitric acid under pressure in sealed tubes; combustion with calcic hydrate, etc.; but, in my opinion, by far the best and simplest method is that of Nakamura, which is thus described:—

It consists in heating the coal below a red heat in contact with alkaline carbonates, by which the coal, whether bituminous or not, rapidly undergoes, without evolution of smoke, complete atmospheric oxidation in a manner hardly to have been expected. The details of the method are as follow:—Take 3 or 4 parts of the mixed alkali carbonates, or of sodium carbonate, to 1 part of coal in very fine powder. Intimately mix in a large platinum dish or crucible with a dry glass rod, and heat the mixture in the dish or crucible loosely covered, at first so gently as not to volatilise the hydrocarbons—that is, so that no smell, or only a very faint aromatic odour, is observable—a matter much more easy of execution than might be supposed. Use an Argand spirit-lamp instead of a Bunsen burner, to avoid possible absorption of sulphur from the flame of coal gas. Keep at a low temperature for some time; then raise the heat by slow degrees (without letting it reach that of visible redness) until the surface, which is at first of a dark grey colour, becomes only faintly grey. No smoke or odorous gases should escape during the whole of the oxidation. When the surface becomes only faintly grey, raise the temperature to a faint red heat, and keep it stationary for about 40 to 60 minutes, at the end of which time the mass will become almost perfectly white, or reddish if the coal contains iron, from the complete combustion of the coal. The mass is then treated with water, filtered, and the sulphate is determined in the filtrate as usual after acidification. To succeed in the complete oxidation of coal by this method, it is most important to pulverise it as fine as possible. The best plan is to sift it through cotton cloth. . . . Stirring the mixture during the oxidation impedes the process instead of hastening it, probably by closing the passages left by the unconsumed coal.

If the above directions are well carried out, the method leaves nothing to be desired.

It is necessary to distinguish between the sulphur which goes over in the volatile matter, the sulphur left in the coke (which, however, can be converted into sulphurous acid by combustion), and the sulphur which is finally left in the ash combined as sulphate. For this purpose three determinations are required—

1. Total sulphur by Nakamura's method.
2. Sulphur which is converted into sulphurous acid by combustion of the coke in air. This can be done by roasting a quantity of coke representing a known quantity of the coal on platinum foil in a glass combustion-tube, and aspirating the gaseous products of combustion through a solution of iodine or bromine.
3. Determination of sulphur in ash. This can be done in most cases by boiling the ash with a little hydrochloric acid, filtering and determining the sulphuric acid in the filtrate in the usual manner, or by fusion with alkaline carbonates.

#### PROXIMATE ANALYSIS OF AUSTRALIAN SHALE (sp. gr. 1.040-1).

Water lost at 100° C. ....	0.14	Corrected for sulphur.

Fixed carbon .....	5.56	"
Ash .....	15.83	"
Sulphur in volatile matter .....	0.458	"
" fixed carbon .....	0.0121	"
" ash .....	0.0157	"
	100.00	

The practical method partakes of two forms—a partial imitation of the process of gas-making on a small laboratory scale. This method has the advantage of being rapid and fully under control, and being effected in small compact closed apparatus, can be

conducted without any of the losses of a large manufacture, and gives us as a result an ideal that cannot perhaps be entirely reached in a large-scale manufacture; yet tells at once what is in the coal, and what we must try to secure in our works. The other practical method is by conducting a gas manufacture just as in actual practice, with large plant such as is in vogue.

**Laboratory Practical Analysis.**—The apparatus consists of a small and accurate weighing-machine, provided with an arm scaled to hundredths of a pound and capable of easily turning to this quantity. A cast-iron retort 3ft. 6in. long, of D section 5×3½, closed at one end, set horizontally over a furnace, with flues so arranged as to admit of its being evenly heated to any required reasonable temperature. A length of about four inches of the open end is left clear of the brick-work, to provide for the mouthpiece lid and ascension pipe. A chimney, fitted with a damper, is arranged in connection with the flues, to create a draught capable of regulation. The open end of the retort protruding from the brickwork has fitted to it a lid or door hinged on the left hand side, fitted with a cross-bar, which engages in a catch in the right hand side of the mouth of the retort, and a screw arrangement for pressing the lid to the end of the retort so as to hermetically close it, both mouth-piece end and door being properly faced.

On the top of the protruding end of the retort, and at right angles to it, a 2in. pipe, provided with a cock, is screwed in to form the ascension pipe and valve for closing it off from the other apparatus. From the ascension pipe, a rather smaller one (say 1½in.) is carried at a height of about 7ft. from the floor, so as to allow of head-room, and is turned down again to connect to a condenser conveniently placed against a wall, so as to be out of the way. This condenser is made up of about 60ft. run of a ¾in. pipe, provided with cocks to run off the tar and liquor which collects. These pipes are placed in a water tank. The inlet to the condenser is fitted with a cock, and the outlet to two small cast-iron purifiers, 12in. × 12in. × 6in., having cast-iron lids dropping into water-tubes cast on the sides of the purifiers. The weight of these lids is sufficient to hold them in their places without fastening. The inlet to these purifiers is at the bottom; and about 2in. above, on small feet, is a wooden grid to hold the purifying material (moist slaked lime), a small tube-like arrangement is cast on the inside leading from the top to the bottom, down which the gas passes, after having traversed upwards through four inches of lime, and then by a piece of gas-piping to the inlet of the second purifier, which is similar in all respects to the first. To the outlet of the second purifier is a pipe leading to the inlet of the gas-holder. This gas-holder has a capacity of about 12 to 13 cubic feet, and carries on it a vertical brass scale accurately divided into cubic feet, tenths and hundredths. The holder works in a cast-iron tank filled with water, and is fitted with rollers, top and bottom, for guiding it in its passage up and down. The rollers at the top are two in number, and work against a guide-rail placed on two upright pillars mounted on the top of the tank, opposite each other. These pillars are connected by a cross-head, whereon is mounted a wheel, over which travels a strong wire cord, connected at one end to the centre of the crown of the gas-holder, and at the other to an iron rod and circular plate, to carry the counterpoise weights—slotted circular discs of cast-iron. A pipe which passes up through the tank above the water-line serves as inlet and outlet by an arrangement of 3 cocks on each leg of a T piece placed outside. The gas can be caused to either enter the holder from the purifier, or go out from it to the photometer, or go from the purifier to the photometer

direct, without communication with the holder. To compensate for the increasing weight of the gas-holder when rising out of the water, a special counterpoise is arranged, which need not be specially described. The crown of the holder is flat, excepting at the centre, where there is a sort of cap just over the ascending pipe, which is a few inches above the crown when the holder is down. The object of this is to enable the water to nearly fill the crown of the holder without flowing over the top of the ascending pipe, and thus stopping the flow of gas. As even then some water might by accident get over, a small plug or tap is placed in the pipe outside the tank to admit of the removal of such water. A thermometer and water-gauge are mounted with the holder to indicate the pressure and temperature. When gas is entering the holder from the retort during an experiment, the holder is counterpoised so that the water-gauge is level. When it is desired to remove gas from the holder, as in testing it by the photometer, weights are taken off the counterpoise rod to produce any convenient pressure. Before commencing a trial, some of the coal to be tried is placed in the hot retort, and the gas allowed to enter the holder. This gas is blown back, and burnt at the mouth of the retort, the cock in ascension-pipe then closed, and the residue in the retort carefully raked out. Thus the whole apparatus is charged with gas of similar nature to that to be examined. Then the cock leading from the holder to the photometer, and the cock on the ascension-pipe being closed, and all other communication open, a quantity of 2¼lb. of the coal, or 1000th part of a ton, is introduced by means of a suitable long iron scoop into the hot retort and turned over. Three simultaneous operations have now to be performed. The scoop has to be drawn rapidly out with the right hand, and dropped; the left hand closes and screws up the lid or door of the retort, and the right hand being free, opens the cock on the ascension-pipe. With practice, this combined operation can be so performed that no gas escapes. The gas then passes through the condenser and purifier into the holder, and in a quarter to half-an-hour, according to the heat and nature of the coal, all gas is extracted. To ascertain when this is complete, the gas-holder scale can be watched till it remains stationary. But I prefer also placing a water-gauge on the pipe leading to the condenser, and by shutting the tap on the inlet before mentioned, observing whether there is any movement of the gauge, which there would be if any gas were coming from the retort. This point satisfactorily settled, the cock on ascension-pipe can be closed, the retort door opened, and the coke raked out into an iron pan, and carefully weighed. The tap on the inlet gas-holder being closed, and the one leading to the photometer open, the illuminating power can be determined according to usual methods. It will be observed that this apparatus, as above-described, only provides for three results. (1.) The quantity of gas. (2.) Its illuminating power. (3.) The weight of residual coke. But by means of a conveniently-designed condenser, I have found it possible to obtain a fairly accurate idea of the quantities of tar and gas-liquor yielded; but, as no scrubbing operation is arranged for, the total quantity of ammonia is not obtainable. These two quantities—the tar and ammonia—are generally neglected on this form of testing apparatus; the chief desideratum being a rapid means of finding the gas-making value of the coal. The volume of gas, if collected in the holder, is of course corrected for temperature and atmospheric pressure to the standards of 60° F. and 30" Bar. by means of the table on pages 660 and 661.

This apparatus, properly and intelligently handled, gives results of the utmost value to the gas-maker;

## ILLUMINATING POWER OF GAS.

To Correct the illuminating power in Candles DIVIDE by the Tabular number due to Temperature and Pressure.

Gas Office, George Street,  
Nottingham, July, 1885.

but since there are no losses, as in a great manufacture, and for other reasons to be explained later, the results are always higher than those found in actual working practice. They give, subject to what I shall have afterwards occasion to remark respecting influence of temperature, and containing vessel of distillation, what is in the coal, and what the gas-maker must endeavour to produce on the working scale.

For many reasons, in a large gas undertaking it is desirable to have more practical and extensive information concerning the quality of various coals, and their all-round behaviour in large working plants that experience has evolved. For instance, the retort now-a-days must be of fire-clay, the cost of wear and tear of iron being prohibitory. Then an exhaustor is required to relieve the retort of pressure, since a system of counterpoised holders would not be practicable. To enable coal to be tested under the actual conditions obtaining in a modern gasworks, the Gas Committee of Nottingham decided to erect a small gasworks, which is to all intents and purposes part of the manufacturing plant. At one end of one of the retort houses was a coal store, and in this was erected exhausting, condensing, scrubbing, purifying, and gas-measuring plant capable of dealing with one, two, or three sets of retorts in regular work. Thus the expense of any special buildings, retort settings, and gas-holder was obviated, the simple addition being the plant above-mentioned. Thus, gas from sets of retorts as ordinarily worked, could be separately measured and examined, and the fullest information obtained in a practical and useful manner concerning any coal. The hydraulic main connected with the above-mentioned three sets of retorts was by means of diaphragms made into three sections, one for each set, and by suitable arrangement of pipes and valves one, two, or all of these sets could be connected with the special testing plant, or with the plant of the regular gasworks. The gas, then, from one, two, or three sets can be separately carried to a Pelouze and Audouin condenser, then to a steam jet exhauster water condenser, two scrubbers (one for washing the gas with ammoniacal liquor and the other with clean water), to two purifiers charged with lime, small station meter that had been in use for a somewhat suitable purpose, and was of admirable construction and ample size for the purpose, and finally to one of the works' gas-holders. By proper arrangements of steam traps and governors a very perfect vacuum is secured (this is a point of utmost importance), all the connections and plant are of sufficient size, so as to avoid obstructions and to prevent undue and unequal resistances. Thermometers and water gauges are connected to every important part of the apparatus. A small steam pump for circulating the liquor through the first scrubber, water meter to measure the quantity of clean water added, and proper valves to all the plant. The station meter was brought to exact agreement by numerous tests with a standard test meter, made by a celebrated maker, which corresponded accurately with two standard gas-holders made by different competent makers. The whole plant from retorts to meter is perfectly open to observation, and the pipes are above ground. There has been no trace of leakage, but any would be immediately observed. The seals of condensers and scrubbers are connected to a tank accurately made, so as to contain 10 gallons to the inch. In this the tar and liquor made is measured, but as it is sometimes difficult to find the exact level of separation between the tar and liquor, the former at the end of every twenty-four hours is pumped into a separate measuring tank, to confirm the measurements obtained from the other. The coal to the setting of retorts—each of which consist of fourteen single or seven through retorts, 18 x

13, D section, 18 feet through—is weighed on a machine continually checked, but examined also once a year, together with all the others in the works, by the maker. The weighings are also checked by the gross and tare weights of the coal wagons as they come in and go out of the yard. The coke drawn out is also accurately weighed, and its quality and appearance observed. The retorts are charged as regularly as possible to obtain the proper regularity of quality, and generally carry 2 cwt. charges in five hours; but this, of course, is varied if required. In that manner the normal weight of coal per set per twenty-four hours is 6 tons, 14 cwt., 2 quarters. No charge is drawn unless properly burnt off. Each hour the meter index and thermometer and jet photometer and Giroud's verificateur readings are taken and recorded. Every two hours the gas is further tested in a first-class photometer provided with a Methven standard burning town works gas, which is of very regular illuminating power. Daily the gas, on outlet of scrubbers, is quantitatively tested for the slight trace of ammonia which occurs in gas, washed clean to litmus paper; for sulphuretted hydrogen carbonic acid gas and cyanogen compounds. Samples of tar and ammoniacal liquor are taken and tested, a quantity proportionate to the day's make being saved and collectively analysed at the completion of the trial, which generally lasts seven days to secure a good average. Every day also the gas is tested for CS<sub>2</sub>. The volume of gas registered is corrected daily by the average of the thermometer readings of the meter and barometer records, by means of the table before referred to. Every effort is made to secure absolute accuracy of observations, and various analyses not above specified are made from time to time, to obtain a knowledge of the coal and its products of distillation, and in contiguity to the two plants is a chemical laboratory, where the analyses are made by approved methods.

With a large testing works like the one at Nottingham, it will be evident that on first starting a trial after the plant has been standing, say for some days, a little time will be required to get it into normal working, since the seals and other parts are charged with tar and liquor from a previous trial of perhaps a totally different coal; the scrubbers, condensers, etc., are drained free from liquid products, and the whole apparatus is filled with stale gas; and even if the plant has been in work immediately before changing over from one coal to another, some of the above conditions will apply. For reasons founded upon the above and similar considerations, the first 24 hours' work, though accurately recorded, is not to be considered satisfactory. We generally arrange for a week's working, which, with the deductions of the first day and Sunday, gives a five days' average. It will be useful to state that subject to the influence of temperature of distillation, as indicated by the volume of gas made per ton, the result "candles per ton," from one day to another is generally satisfactory, and even when an occasional discrepancy arises, it is due often to difficulties in photometer testing, and would be removed if, instead of calculating the results from the bar photometer, we employed the average of the hourly readings of the inferential tests, such as Giroud's verificateur or Lowe's jet photometer. The yields of coke and tar from day to day are fairly concordant, but the variations of ammonia are always large and quite outside any possibility of experimental error. This matter of ammonia has received a deal of attention, and the results must be accepted as an index of the true behaviour of this nitrogen product of coal distillation. We find in testing the crude gas of our gas works the same variations from hour to hour, and I have frequently had occasion to observe this

peculiarity in London. I have been making some inquiries into the cause of this variability, but up to the present am only in the position to say that it is not due to certain influences I had suspected.

From a proximate analysis alone we can gather but little information as to the value of a coal for gas-making purposes; it might expose a bad coal, but could hardly make as sure of a good one. The coke

\* This cannel is from an entirely different seam to that which produces the cannel that heads this list.

It will be expected that I should say something about the practical values of the various methods of analysis.

As to elementary analysis, can one, from an inspection of numbers giving the elementary composition of a coal, offer a positive or even approximately valuable opinion concerning its uses to a gas-maker? I would reply certainly not, as far as our present information goes. It would take too much time to enter into my reasons for this statement, but an inspection of published analyses and gas-making results of various coals will, I think, convince anyone of the justness of the above-expressed opinion. I think, however, that, where possible, an elementary analysis should be made of samples under practical test, for the composition of the same seam varies so, that unless the two analyses represent the same bulk, anything like a close comparison could not be made.

It is equally impossible also to form a definite or valuable judgment of the gas-making properties of a coal from the proximate analysis. Of course, broadly, we can assume that the gas-making value varies with the volatile matter, less moisture—for instance, Australian shale, with 77 per cent. v.m., gives 140,000 candles per ton, and a Derbyshire or Yorkshire coal, with 35 per cent. v.m., about 35,000 candles per ton.

For absolute practical information respecting a gas-making coal, we are driven to a practical analysis.

As to the value of proximate analysis—when other practical methods are used, the results peculiar to proximate analysis—viz., volatile matter (not including water at 212°) and coke are not so valuable, except perhaps in confirming what is found in practice.

result accords, in my experience, remarkably well with the more practical ones. Thus, a Derbyshire coal gave 38 per cent. v.m., leaving 62 per cent. of coke, or 12.4 cwt. per ton. The laboratory practical analysis with iron retort (9 experiments) 12.37 cwt. per ton, with clay retorts (27 experiments) 12.39 cwt. per ton. In another case—

Proximate analysis.....	63.83 per cent., or 12.76 cwt. per ton.
Laboratory practical analysis.....	12.77
Works practical analysis.....	12.69 " "

The laboratory practical analysis with iron retort is of great value, but it will be necessary in interpreting the results to recollect that the method of heating the coal is different to that used in practice with clay retorts. In the former, the heat is quickly conveyed through the metal vessel, and there is no doubt in my mind that an iron vessel exerts a chemical action upon the gas made therein. As far as volume and quality of gas are concerned, we always obtain better results with the small iron retort than with clay.

But it is most important to consider the influence of temperature upon the results. It is customary to consider that within certain practical ranges of temperature the product of volume of gas yielded by its luminosity—i.e., cubic feet per ton  $\times$  illuminating power per cubic foot per hour—is a constant for each coal. As we decrease the one factor, we proportionately increase the other. When we say that a ton of coal contains—say 9000 cubic feet per ton, we do not mean that there is that fixed quantity and no more nor less in it, but simply that under certain conditions of distillation that quantity of coal yields 9000 cubic feet,

and it is implied that by either raising or lowering the mean temperature of distillation, more or less gas of more or less luminosity is produced. Now, it is important to enquire whether the variations in the two factors are proportional to each other, or, in other words, whether the product of quantity by luminosity is a constant for each coal. It is difficult to know what is the current opinion on this point. Dr. Schilling in his "Handbook of Coal-Gas Lighting," speaks of the economy of "high heats" in a general manner, but also publishes the following table, from which it might be inferred that with an increase in the "heat" there is a decrease in the total luminosity afforded by a given weight of coal.

	An increased yield of gas.	A decreased illuminating power.
Zwickau Coal.....	18 per cent.	14 per cent.
Saarlück Coal ...	18 "	21 "
Bohemian Coal ...	25 "	30 "
Old Pelton Coal ...	24 "	38 "
Westphalian Coal ..	15 "	40 "
Stockheim Coal ...	20 "	42 "

With the exception of the first result on the list, my own experience differs from his, for I have always found, with carefully and properly conducted experiments, that with any coal I have experimented with, the product of volume by illuminating power increases with the volume.

In a paper on the influence of temperature of distillation in the composition of coal gas, to be found in the *Journal of the Chemical Society*, March, 1884, I showed the influence of temperature in bringing out the light-affording power of coal, thus:—

Gas coal distilled at a temperature to yield in cubic feet per ton.	Illuminating power per 5 cubic feet per hour.	Candles per ton, or yield by candles per cubic foot.
8,250	20.5 candles.	33,825
9,693	17.8 "	34,510
10,821	16.75 "	36,250
12,006	15.6 "	37,460

Taking the first and last results, we find that with an increased yield of 45½ per cent., there is only a decrease in the illuminating power of 24 per cent.; and that there is a net gain of 11 per cent. by working at the higher temperature. The following table will indicate this for a number of different coals. It is important that I should emphasise this fact that the product of volume by illuminating power increases with the volume.

I have before compared the yields of coke obtained by proximate analysis and practical methods. I now propose to consider the results obtained by the two practical methods in ordinary use—viz., the small iron retort and setting of clay retorts identical to those used in regular gas manufacture. The iron retort is one inch, the clay retorts are three inches thick. For the same temperature difference between the inner and outer surfaces of these vessels, there is in the same time 170 times more heat passed through the iron than through the clay. The flue or outside temperature employed in the clay settings if applied to iron retorts, would bring them like water running into the fires in a few hours. Yet in working iron retorts in perfect safety, it is possible to get an efficiency of 140 cubic feet per square foot of heating surface out of them, a result much above the average of clay retorts. The apparent temperature applied to the coal is less with iron than with clay. Yet the effective temperature in distilling coal can be at least as great as is customary with the latter. Any determination of the practical or effective temperature of retorts by pyrometer at the end of a charge, or by the colour or appearance of the retort, is likely to prove illusory, for it is easy to get up a good appearance in them by undercharging. The best test to my mind is the amount of work they will perform in distilling coal expressed by the quantity of gas produced per superficial foot of heating surface per 24 hours.

I have found that with the small iron retort a better result is always obtained than with the large experimental works, but the difference varies with the kind of coal. With the very finest coking coals the difference is very small, and as the coking quality of the coal decreases, so the difference between the two methods of testing increases. With coals (not cannels) which scarcely intumesce at all the difference becomes very high.

Cannels also vary in the same manner, the difference in the results being always connected with differences in the qualities of the residues of distillation or cokes. This point is illustrated in the following table:—

	CLAY RETORT.		IRON RETORT.		Difference per cent.
	Cubic ft. per ton.	Candles per ton.	Cubic ft. per ton.	Candles per ton.	
Average of 12 Derbyshire and Yorkshire Coking Coals.....	10,110	33,600	11,010	36,600	9
Average of 5 Derbyshire and Nottinghamshire Non-Coking Coals.....	9,156	27,330	10,430	33,820	23
Average of 14 Cannels from various Districts .....	9,930	42,360	10,630	49,850	18

I have stated the volume of gas produced per ton, so that in regarding the above figures, allowance can be made for difference naturally due to temperature, as measured by yield of volume.

Since the gas from the iron retort was not scrubbed, a deduction of about 3 per cent. should be made from the results of the small apparatus, to compensate for the slight loss of illuminating power suffered by the gas of the large experimental works in the washing process. When this allowance for washing is made there is really little difference between the two methods of testing in the case of caking coals, but the difference is quite irreconcilable with some coals. There are two cannels of a shaley character included in the above average of 14 cannels, which give differences of 22 per cent. and 31 per cent. respectively; and it is remarkable that these two materials yield residues on distillation hopelessly valueless as fuel, being little else than an earthy ash. The one which gives a difference of 31 per cent. was introduced to me with a splendid analysis made probably in an iron retort. On submitting the coal to test, it was found to be of very little value when carbonised in clay retorts, though it tested fairly well in the small iron vessel. It is known that the weight of the fixed residue of distillation in proximate analysis is dependent on the manner, degree, or extent of heating, and I have shown above that the amount of valuable gaseous products obtained from a coal will vary with the manner and extent of heating; and further, that the nature of the base or fixed residue of distillation has an important influence on the behaviour of coal submitted either to rapid or to slower distillation. It is within my experience as a gas-maker that with the same coal the character and appearance of the coke produced in gas manufacture is largely affected by the method employed in carbonising it. I have in my mind a class of coal the smudge from which produces the finest furnace coke (when coked in beehive ovens) in the world, and which is regarded by gas-makers as a splendid gas coke producing coal. This coal, if carbonised in clay retorts, working off 2cwt. charges in 5 hours, and affording about 115 cubic feet of gas per 24 hours per square foot of heating surface, gives a fine large metallic looking coke of hard steely appearance. If the retorts are worked at a higher average temperature, so as to burn off the 2cwt. charge in 4 hours, and to produce about 140 cubic feet of gas per square foot of heating surface, the coal will give a coke of inferior appearance to the other, being smaller and less metallic in appearance, with many black pieces. If carbonised in iron retorts carbonising 1½ cwt. in 5 hours, and giving 140 cubic feet of gas per square foot of heating surface, the coke is small, black, and of appearance much inferior to the others.

Enough has been said to show that the results given by the small iron retort in common use for testing gas-coals cannot be accepted as authoritative in these days, when only clay retorts are used in large works; and it must be in the experience of all gas manufacturers that many coals do not justify in practice the values assigned to them by analysts, who use what is called the laboratory analysis. It will be interesting also to know how far the results obtained in our gas works agree with the values assigned to the various coals we use by the experimental works in which they are all tested. I have carefully compared for a long period the actual working results of our daily manufacture with the theoretical average value of the mixture of coals and canal we employ, calculated from the values of the respective coals as determined in the experimental works in their various proportions, and I find that we exceed in practice the theoretical field so calculated by 3 per cent. This amount is not large, but it is constant, ranging from about 2 to 4 per cent.; and is further, I believe, beyond the range of experimental error. This slight improvement is no doubt due to the admixture of low and high power gases,

obtained from a 70 per cent. of coking coal, and 30 per cent. canal coal before condensation commences, with the result that the low power gas carries forward some of the hydrocarbons of the canal gas that would otherwise be condensed and removed from the gas by the tar. I may say that our station meters have been compared and standardised by the same standard meter used for standardising the experimental works station meter, and that the illuminating power used in calculating the candles per ton we obtain in our manufacture is the average of our official tests made in the centre of the town.

It is unfortunate that we have no proper classification of all the various kinds of coal which nature has produced. Such terms as caking splint coal, cherry coal, peacock coal, canal coal, slate coal, leaf coal, coarse bituminous, semibituminous, are not sufficiently explicit. The Germans, I think, have a better, but even theirs I find wanting, as it is customary to classify a non-homogeneous coal, consisting of many varieties, under one name that may express its few united qualities more or less perfectly, but not satisfactorily. A piece of coal I have selected for your inspection contains at least three widely different kinds, first you will see layers of vegetable charcoal, then a material very like pitch, and finally canal coal. The part forest fires may have played in the formation of these qualities has not received attention. It is difficult to examine this coal without imagining that it is the final result of charred wood fibre. The pitch having been a distillation product, and the canal coal which occurs in a basin or huge pond, being an earthy base permeated with tarry distillation matters, and deposited in a liquid form. It is very common to find these three sorts of coal in contiguous layers, and yet the coal may be classed as caking coal. The Germans, I think, have given the names *Russkohle* and *Pechkohle* to the two first-mentioned varieties, but it is difficult, of course, to know always what German writers understand by the numerous titles they have for different sorts of coal. A complete classification and examination of our various British coals is wanting, and we have, I am sorry to say, no work similar to the extensive work of Drs. Geinitz, Fleck, and Hartig, on the coal of Germany. I fear we are accustomed to leave too much to individual effort.

*Estimation of Sulphuretted Hydrogen and Carbonic Acid in Crude Coal-Gas.*—For many reasons I prefer, for the estimation of hydrogen sulphide and carbonic anhydride in impure coal-gas, a method founded upon the increase in weight of absorption tubes; a method which will admit of the use of a tolerably large quantity of gas collected regularly during an interval of time sufficiently long to afford an idea of the average composition of the gas supply to be tested.

I have adopted as the reagent for absorption of hydrogen sulphide in absorption-tubes, a cupric phosphate, which is an impure di-, tri-, ortho-phosphate.

The cupric phosphate for use in absorption-tubes is prepared somewhat in the following manner:—

Solutions of—

2lb. hydrogen disodium phosphate in 1 gallon of water, and

2½lb. cupric sulphate crystals in 1½ gallons of water, are mixed with vigorous stirring, and the resulting bright blue precipitate washed by decantation and then dried in a water-bath to about 100°. The material sometimes is light and powdery, sometimes hard, and then requires crushing in a mortar. Its action with hydrogen sulphide is very sharp indeed.

The U-tubes used in these experiments are preferably of the new form with hollow glass round stoppers, serving as stopcocks, the inlet and outlet

connections being small pieces of glass tubing fused into the sides or the tubes. A small hole in the stopper corresponding to the hole in the side of the tube, where the small glass tubing is fused on, makes the connection. A small turn of the stoppers closes or opens the tube. The tubes are weighed charged with clean coal-gas, which on the same gas supply, varies but little in specific gravity.

The stoppers are lubricated with resin cerate, and with this exception are perfectly clean. A small plug of cotton-wool in each stopper prevents the mechanical carriage of fine proportions of the reagents by issuing gases. Under these circumstances, I find that closed tubes charged with coal-gas suffer no appreciable variations in weight during a period of two days. These tubes are very useful indeed, and are far superior to the old form with corks.

I find that absorption-tubes charged with cupric phosphate gain in weight under the action of clean coal-gas; but the increase of weight soon reaches a limit, and the phosphate becomes "saturated," and to attain this saturation 3 cubic feet of clean dry coal-gas should be slowly passed through the tubes.

The phosphate tubes are charged in the following manner. The tubes are cleaned and dried, great attention being paid to the ground portions of the tubes and stoppers. A plug of cotton-wool is placed in the bend of the U-tube. Then one leg of the tube is charged with the cupric phosphate in a suitable state of subdivision, care being taken that the rough and fine portions of the powder are regularly distributed, for if all the rough portions are on one side and the fine on the other, a passage of the gas down the side where the coarse portions are takes place, and the finer portions never come into action. The other leg is charged with powdered calcium chloride. The ground portions of the tubes are wiped free from dust, and the stoppers, fitted with plugs of dry cotton-wool in the hollow places, are lubricated with a little resin cerate, and put in position. A current of dry gas-coal to the extent of 3 cubic feet is passed through, and the tubes are ready for weighing. A 6-inch U-tube charged in this manner will be capable of absorbing 20 grains of hydrogen sulphide, and if in the case of gas containing 10 grains of hydrogen sulphide per cubic foot, the experiments be made upon quantities of half a cubic foot, each will therefore serve for four analyses without being recharged. The calcium chloride will serve much longer.

The soda-lime tube for carbonic anhydride absorption is charged in the same manner, one half full of soda-lime, and one half of calcium chloride. I have found it necessary to use the soda-lime in a moist condition, for, when quite dry, soda-lime has a much feeble absorptive power for carbonic anhydride.

The requisite degree of moistness is attained by exposing it to a moist atmosphere for 12 to 18 hours. There are no inconveniences attending soda-lime in this condition. These soda-lime tubes remain very constant in weight when clean pure coal-gas is passed through them, and therefore do not require saturating in the same manner as the phosphate tubes: a small quantity of dry pure coal-gas should, however, be passed through to expel air, previous to their being weighed.

A 6-inch tube, charged with soda-lime in the manner above described, serves for three analyses of half a cubic foot each on gas containing 10 to 12 grains carbonic anhydride per cubic foot.

In cases where ammonia also exists in the coal-gas to be analysed for hydrogen sulphide and carbonic anhydride, it will be necessary to effect its removal before the coal-gas reaches the weighing tubes. That calcium chloride effectually removes ammonia from coal-gas I have frequently had occasion to notice,

and Dibbitts (*Zeits. für Analyt. Chem.*, 15, 1876, 124) has made the same remark. But to maintain the neutrality of the calcium chloride I remove the ammonia from the coal-gas before drying, and for this purpose pass the gas through a 12-inch U-tube filled with broken pumice saturated with syrupy phosphoric acid.

In the drawing off of samples of coal-gas for analysis, certain precautions are indispensable, since vulcanised and iron tubing when new remove hydrogen sulphide from crude coal-gas, so that it is necessary to have the services conducting the coal-gas from the source to be tested to the absorption-tubes as short as possible, and saturated by previous use with crude coal-gas. It is further of importance to keep a tolerably quick current of gas through the iron pipe, in order to prevent the gas from getting "stale."

The iron service should be fitted with a four-way piece and three cocks. One serves to take the gas to the train of apparatus; another to be left open during the analysis, blowing gas away, and thus maintaining a rapid current in the iron pipe; the third cock can be used for other purposes, such as examination of the gas for ammonia, &c. Before making an analysis it is necessary to blow a little gas away in order to clear stale gas out of the iron service-pipe, and to bring a fresh supply along.

The complete apparatus for the estimation of hydrogen sulphide in coal-gas can now be described.

The first piece in the train is the syrupy phosphoric acid tube, which can however be dispensed with in cases where the gas has been thoroughly washed free from ammonia. This tube is directly connected with the cock on the iron pipe by means of a small piece of "saturated" vulcanised tubing. The outlet of this tube is connected to a large drying cylinder filled with small pieces of calcium chloride free from alkalinity. The outlet of this drying cylinder is a T-piece, which carries on one arm a small piece of vulcanised tubing and screw-clamp for the purpose of blowing a little gas away before and during each experiment. The other arm of the T-piece is connected to the inlet of the cupric phosphate tube, which in its turn is connected with the soda-lime tube, and a gas meter connected to the outlet of the soda-lime tube completes the apparatus. The meter most suitable for the purpose is the test-meter, as used by the gas referees for the "sulphur" test. It is advisable to bring the pointer up to within a division or so of the zero by means of the key, and then to blow through until the pointer exactly covers the mark. Any error due to slackness in the gearing of index is thus avoided. Before starting an experiment, gas should be blown away at the outlet of the drying cylinder, as well as at the cock on the iron service.

When the tubes have been weighed full of clean coal-gas, and all the pieces of the train properly joined together, the stopcocks are turned on, and the gas allowed to traverse the apparatus at a moderate rate, which is often more dependent on the pressure of the gas than the will of the operator. From a quarter to one half a cubic foot per hour is a convenient rate, and one well within the limits at which the complete action of the reagents is obtained.

The quantity of gas used for each experiment is a matter of choice, and will be determined by the quantity of impurity in the coal-gas under analysis.

When the required quantity of gas has passed through the tubes, the inlet stopper of the phosphate tube and the outlet stopper of the soda-lime tube are turned off, and the two tubes are taken off together, and connected in their proper order to a supply of desiccated clean gas, in order to drive the gas in the phosphate tube through the soda-lime tube. The

stopper can then be turned off and the tubes weighed. Of course, before weighing these tubes, they must be wiped perfectly clean and dry; but as this operation causes them to be a little light, they should be left for about five or ten minutes in the balance case before being weighed. The results corrected for temperature, &c., are best calculated to a cubic foot of clean coal-gas at 60° F. and 30in. barometer.

Since washed but otherwise unpurified coal-gas contains about 6 grain per cubic foot of cyanogen, the results obtained by this method are slightly high. The absorption of cyanogen in the cupric sulphide is not complete, about one half going forward into the soda-lime tube. The error falls equally on each tube.

*Cyanogen*.—This body is estimated by passing a measured quantity of gas free from ammonia, but otherwise unpurified, through a U-tube filled with soda-lime, and then making a combustion of the residue as in an ordinary nitrogen determination.

## INTERNATIONAL INVENTIONS EXHIBITION, LONDON.

### ADDENDUM TO REPORT ON THE EXHIBITS RELATING TO THE CHEMICAL INDUSTRIES.

BY WATSON SMITH,

Lecturer in Chemical Technology in the Victoria University, Manchester, etc.

\* J. C. & J. FIELD, LONDON (Group XI. No. 1192).

*Beeswax*.—Specimens were shown of the wax, air-bleached and bleached by the potassium bichromate method. The latter process, whilst giving the whiter product, yields a crystalline wax less suitable for burning than for the use of druggists.

Samples of church candles and carriage lights made from the wax were shown, and it is stated that Messrs. J. C. & J. Field made wax candles in 1680.

*Spermaceti*.—This is purified from the "head-matter" and crude oil by "bagging," or a process of filtration in which the weight of the substance is made available. About ten per cent. is recovered. Melting-point, 43° to 44° C.

This material is used for high-class candles, popular on account of the absence of the tendency to bend when placed in a warm atmosphere. Specimens of standard sperm gas-candles were shown, burning 120 grains per hour.

I am informed that Messrs. J. C. & J. Field made the first sperm candles in 1760, and that over 220 tons of wax and spermaceti are now manufactured per annum by the firm, about 400 tons of wax and sperm candles being employed in England and Ireland alone.

*Stearin*.—Specimens were shown prepared both by the "autoclave" process and by lime saponification. The product of the latter process shows the highest melting-point—viz., 56° C., and is better adapted for working up inferior greases.

The original candles from Milly et Cie., "*Bougies de l'Etoile*," imported by J. C. & J. Field in 1835, were exhibited.

*Paraffin*.—The cruder material is refined by treatment with naphtha, and by the "banding" process—i.e., passing through cogged wheels in an alkaline solution, which emulsifies the coarser oils. Melting-point of the refined product is about 51° C. J. C. & J. Field state that they were the first to make paraffin candles, and that they originally contracted

with the Irish Peat Company and Young's Paraffin Company for the sole supply of their produce.

*OZOKERITE*.—Introduced by F. Field, F.R.S., in 1872. The crude product from Galicia is treated with superheated steam, when a purer paraffin distills over. The distillates obtained are—

- (i.) A gaseous hydrocarbon, to the extent of about five per cent.
- (ii.) A volatile naphtha. (About three per cent.).
- (iii.) A "vaseline" product called "Ozokerine." (About six per cent.).
- (iv.) A soft paraffin. (About twelve per cent. Melting-point 44½° to 46° C.).
- (v.) A white paraffin (*Ozokerite*), with a melting-point of 61° C.
- (vi.) A black waxy residual melting at 77° C.

The gas and naphtha are said to be useless. The ozokerine has a sale amongst chemists and hair-dressers and in the hospitals, as a basis for pomades and unguents. It is also imported to France (Grasse) as a substitute for lard in "*enflourage*." The soft paraffin is employed in the manufacture of cheap candles, retailing at 3d. and 1d. This employment gave rise to the use of paraffin scale for that purpose, which has resulted in the death-blow to the tallow and composite candle trade.

*The White Paraffin*, Ozokerite proper, is employed for making the well-known ozokerite candles, which, it is stated, melt not only about six degrees (Centigrade) higher than any other paraffin or stearin candle, but bend at a much higher temperature. The flame of the candles is small and very brilliant. It is stated that equal candles of ozokerite and sperm give lights differing in the ratio of 10 : 7.

*The Black Paraffin* is largely used by electrical engineers as an insulator. Matthiessen found that it gave more complete insulation and possessed less induction capacity than any other known substance.

F. Field has patented an elastic compound of this wax with indiarubber, which has been adopted to some extent in the manufacture of cables.

*Ornamental Candles*.—Of these a large number is exhibited. Messrs. Field state that they patented every description of ornamental candle now made. The cable candles they still make with the lathe, having abandoned the machine, as giving results good, it is true, as regards quantity, but not equal as regards quality to the lathe candles. It is stated that by the use of the lathe patented by Messrs. Field, eighteen varieties and sizes can be turned out, ornamented with vertical and spiral stripes and six different cable patterns. To do this otherwise would require a corresponding number of machines, and certain varieties of the ornamental candles referred to cannot be made by any other than the lathe method.

*Self-fitting Ends*.—Of these Messrs. Field state that they were the original patentees, and for fourteen years have been the sole manufacturers. They still retain the original form—namely, with broad obtuse angled flutes, stating that ends shaped thus, by spreading out, perpetually resist the pressure, being fixed in their receptacles after the manner of wedges. The firm has, moreover, patented a very simple "wedge-end," which has the advantage of being made all in one piece like an ordinary candle.

*Aerated Candles*.—The patent for these was taken up in 1870 from M. Urbain. At the Exhibition the candles were made in a French machine, which for simplicity and efficiency appears superior to the English specimens. The rods which produce the perforations in the bodies of the candles are so constructed as not to crack the sides when withdrawn.

\* Omitted on page 563, through information arriving too late for press.

**Candle Machinery.**—Besides the machine last referred to, Messrs. Field exhibit a new patent machine for making the self-fitting ends. In the old method the caps that moulded the conical butts are withdrawn simply by hand, and replaced in the same manner, entailing a great deal of labour and sacrificing a considerable quantity of wax. In Field's machine a lever separates the coned moulds, thus allowing the candle to be wound out in the ordinary way. The time taken in liberating one set of candles and filling another is five minutes, in the old machine from twenty to thirty.

**Soaps.**—From the oleic acid obtained from the antoclave and saponification processes, J. C. & J. Field manufacture a brand of soap known as the "Pure Oil Soap," much used by dyers, etc. Their speciality in toilet soaps is the newly-patented "Sapphire Soap," which is saponified by the use of iodised potash obtained from the ashes of seaweed, and palm and olein oils. The resulting soap is subsequently milled, after completely expelling every trace of water, and is de-alkalised by the introduction of salicylate of ammonium.

## Journal and Patent Literature.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*An Improved Substance for Lining or Covering Steam Boilers, Pipes, and other objects.* H. J. Allison, London. From Messrs. Sophus, Dohmann & Company, Copenhagen, Denmark. Eng. Pat. 4343, April 8, 1885.

SAWDUST, chopped straw, cork, bark or other similar light substances are mixed with soluble glass and chalk or lime, in a pulverised state. The mixture thus obtained—formed into pieces adapted to the article it is intended to cover—is thoroughly impregnated with a boiling solution of calcium, magnesium or barium chloride or sulphate of alumina, and after washing in boiling water to free it from soluble salts, the substance, which is now combustible, is ready for use.—A. W.

*Improvements in Filters.* E. M. Knight, Liverpool. Eng. Pat. 12,287, September 14, 1884.

A CYLINDRICAL vessel is formed with a concentric perforated cone; this is covered with asbestos cloth, and the annular space filled with charcoal, held down by a perforated cover, through which the water to be purified is admitted to the charcoal filtering bed. The whole is suspended in a porcelain vessel of the usual shape.—C. C. H.

*Improvements in Filters.* P. A. Maignen, London. Eng. Pat. 13,315, October 8, 1884.

THE conical or V-shaped filtering frames, such as hitherto used by the patentee, are made so that the lower part forms a wedge joint with the side of the vessel in which they are placed.—C. C. H.

*Improvements in Filters.* C. E. Gittins, London. Eng. Pat. 14,019, October 22, 1884.

THE filter consists of a series of chambers formed from perforated plates and distance frames. These are arranged alternately as supply and discharge chambers, communicating with closed inlet and outlet conduits, as in a filter press. The plates are covered with asbestos or other cloth, and the interior of the chambers filled with charcoal. The whole apparatus is provided with a nozzle, so as to be attached to the tap of a water supply.

—C. C. H.

### II.—FUEL, GAS, AND LIGHT.

*The Influence of Water on the Combustion of Carbon Monoxide, and the Occurrence of Hydrogen Peroxide in this Combustion.* M. Traube. Ber. 18, 1890.

DIXON has shown (*B. J. Rep.* 1880, 503; *Chem. News*, 46, 151; *Phil. Trans.* 1884, 617) that a perfectly dry mixture of carbon monoxide and oxygen cannot be caused to explode either by incandescent platinum wires, or the continued passage of sparks from a Ruhmkorff's coil. The author has found, in confirmation of this result, that carbon monoxide already burning, is extinguished in a dry atmosphere. The author considers the influence of the water to be represented by the following equations:

- (1)  $\text{CO} + 2\text{OH} + \text{O}_2 = \text{CO}(\text{OH})_2 + \text{H}_2\text{O}_2$
- (2)  $\text{H}_2\text{O}_2 + \text{CO} = \text{CO}(\text{OH})_2$
- (3)  $2\text{CO}(\text{OH})_2 = 2\text{CO}_2 + 2\text{H}_2\text{O}$

That hydrogen peroxide is produced in the combustion of carbon monoxide, is shown by bringing the flame of the gas into contact with water, and then showing the presence of the peroxide in the water by the usual tests.

—F. L. T.

*The Production of Hydrogen Peroxide in the Combustion of Hydrogen.* M. Traube. Ber. 18, 1894.

THE author failed to prevent the explosion of mixtures of oxygen (or air) and hydrogen by the electric spark, by having the mixture as dry as he could possibly make it, thus confirming Dixon's results. He confirms Schuller (*Wiedem. Ann. Chem. Pharm.* (1882) 15, 289) that hydrogen peroxide is produced by burning hydrogen in air, and finds by allowing the burning jet to impinge on the surface of water, that 100cc. of water can take up as much as 200mgrm. of the peroxide of hydrogen, figures indicating what seems to be the maximum concentration obtainable. The greatest amount of hydrogen peroxide produced from the combustion of 1 litre of hydrogen, was 0.0113grm. The size and shape of the jet at which the gas was burnt, the pressure, and the amount of air or oxygen, if any, mixed with the gas before burning, all exerted a perceptible influence on the amount of hydrogen peroxide produced.—F. L. T.

*Influence of some Metals on a Mixture of Acetylene and Air.* F. Bellamy. Compt. Rend. 100, 1460—1461.

THE gases are mixed in a glass apparatus resembling a Bunsen's burner. If a platinum or silver wire, scarcely red-hot, be held in the mixture, it causes a detonation, but becomes only seldom, and then transiently and partially, white-hot; on the other hand a red glowing copper wire becomes, in a few seconds, white-hot, and then generally produces an explosion. Iron gives rise to the same phenomena, but with greater difficulty.

—F. L. T.

*Combustion in Dried Gases.* H. B. Baker. J. Chem. Soc. 1885, 349.

AS H. B. Dixon has shown (*Chem. News*, 46, 151; and *Phil. Trans.* 1884, 617) that a dry mixture of oxygen and carbon monoxide cannot be caused to explode by the electric spark, the author has investigated whether moisture is necessary in the combustion of the elements. Amorphous phosphorus, that had been washed with water and dried in a current of carbon dioxide at 100°, and afterwards in a vacuum at 150°, or wood charcoal that had been heated to bright redness in a current of chlorine, were sealed up with oxygen in difficultly-insoluble glass tubes, some of which were slightly bent, and held phosphorus pentoxide in one limb. After about a week the phosphorus and charcoal were heated, but no ignition took place, whilst the same substances placed in similar tubes with moist oxygen, burnt as usual. Similar experiments with charcoal, in which the tubes were raised to redness, showed that, in the dry tubes, about half the oxygen remained uncombined; whereas, in the moist tubes, no trace of free oxygen was present. In the dry tubes visible combustion never occurred. These experiments, and some others where the charcoal

was submitted to the electric spark, show that the absence of moisture greatly retards the combustion of carbon in oxygen.—F. L. T.

*Improvements in Machinery for Deseicating Coal and other Substances at Low Temperatures.* H. G. Fairburn, Cardiff. Eng. Pat. 14,199, January 31, 1885.

THE material to be dried is placed on the floor of a closed chamber, practically exhausted of air, and to which a low external heat is applied. It is caused to move forwards over this floor by the action of a series of loose pendulous prongs, free to move in one direction only, and suspended from a frame, to which a slow reciprocating motion is communicated.—A. R. D.

*Improvements in, or in Connection with, Apparatus for the Carburation of Gas in Railway and other Carriage Lamps and Lanterns.* Peter Jensen, London. From J. E. Dery, Brussels. Eng. Pat. 8816, July 21, 1885.

THESE improvements are upon the apparatus referred to in Specification 10,675, July 28, 1884. Pipes are so disposed and provided with taps that, by suitable manipulation of these latter, the burner may be supplied with gas that either has or has not passed through the carburettor, or with any required mixture of the two.—A. R. D.

*Improvements in and Apparatus for the Manufacture of Coke.* J. Jameson, Newcastle-on-Tyne. Eng. Pat. 14,551, July 31, 1885.

THESE improvements relate to such coke-ovens as the "Jameson," from which the evolved gases are collected and treated for by-products. The gas passages in the bottom of the retorts are partly formed of T iron. This prevents the openings from being injured by the rakes, or from being clogged up by the deposit of hardened oil and dust, which settles upon brick. To provide greater cooling power a vertical pipe is placed between the oven and the main, of half the dimensions of the oven exit. Each of these cooling pipes is provided with a water gauge and an adjustable orifice by which the flow of the gas may be regulated. An expansion bar or pyrometer arrangement may be used to regulate the passage of the gas in an inverse ratio to its heat.—A. R. D.

*Improvements in Coke-Ovens or Retorts, and in Apparatus connected therewith.* John McCulloch, Airdrie. Eng. Pat. 15,821, August 31, 1885.

THIS invention relates to further improvements in the apparatus described in Specification 4122, of 1884. It comprises improved means of exit for the gases from the retorts; combustion chambers or flues combined with furnaces to ensure the perfect combustion of the gaseous fuel used; apparatus for utilising the heat of the volatile products for heating the air; and improved means of quenching the coke. For further particulars, the Blue Book, and its drawings, must be consulted.—A. R. D.

*Improvements in Machinery for Compressing and Solidifying Coal and other Substances.* H. G. Fairburn, Cardiff. Eng. Pat. 616, September 2, 1885.

THE inventor claims "the equal solidification and perfect division of compressed blocks of coal by means of a movable moulding die, working with a reciprocating motion, in line and in conjunction with a retaining tube. For further particulars consult the Blue Book.—A. R. D.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*Brominated Derivatives of Diphenyl, Tolybenzene and Ditoly.* Thomas Carnelley and A. Thomson, J. Chem. Soc. 47, Trans. 586—593.

THE hydrocarbons used in the present investigation were obtained by passing the mixed vapours of benzene and toluene through a ret-hot tube (*J. Chem. Soc.* 37, 701).

1. The diphenyl,  $C_{12}H_{10}$ , after crystallisation from alcohol, melted at 70° and boiled at 245° to 258°.

2. The 1:4 tolybenzene,  $C_{12}H_{10}$ ,  $C_6H_4$ ,  $CH_3$ , was a colourless liquid, boiling at 263° to 268°, and on oxidation gave first 1:4 phenylbenzoic acid, melting at 216° to 220°, and finally terephthalic acid.

3. The 1:2:1:4 ditoly,  $(CH_3 \cdot C_6H_4)_2$ ,  $C_{16}H_{14}$ , was a liquid, boiling at 272° to 280°, and on oxidation gave first 1:2:1:4 tolybenzoic acid,  $CH_3 \cdot C_6H_4 \cdot C_6H_4 \cdot COOH$ , melting at 179° to 180°, and finally terephthalic acid.

*Derivatives of Tolybenzene.*—*Monobromo 1:4 tolybenzene*,  $C_{12}H_{11}Br$ , was prepared by brominating the hydrocarbon (boiling point 163° to 267°) obtained by the action of sodium on mixed monobromobenzene and 1:4 monobromotoluene. The compound melts at 131°, crystallises from alcohol in small pearly plates, and is readily soluble in benzene. *Dibromotolybenzene*,  $C_{12}H_{10}Br_2$ ,  $CH_3$ . Two isomeric modifications were obtained by the action of bromine on 1:4 tolybenzene. By the oxidation of the mixed dibromo 1:4 tolybenzenes, two *dibromophenylbenzoic acids*,  $C_{12}H_{11}Br_2 \cdot COOH$ , were obtained (melting point 202° and 232° respectively). *Monobromoditoly*,  $C_{16}H_{14}Me \cdot C_6H_4 \cdot BrMe$ —1:2:1' : (2' or 3') : 4', was obtained by the action of bromine on 1:2:1:4 ditoly. The product was dissolved in a large quantity of alcohol, from which, on cooling, a brown oil separated, followed by a large crop of crystals. The latter were separated from the oil, and were recrystallised from alcohol. Fine interlacing microscopic needles melting at 93° to 95° were obtained, yielding, on oxidation with chromic and glacial acetic acids, an acid melting at 304° to 309°. The oil referred to above was thoroughly dried and analysed, giving numbers agreeing with the formula  $C_{16}H_{14}Br$ . On oxidation, *monobromodiphenic* and *monobromophthalic acids* were obtained, the former melting at 215° Cor., and the latter at 203° Cor. The constitution of these acids is represented as follows:—*Monobromodiphenic acid*,  $C_{12}H_{11}(COOH)_2 \cdot C_6H_4 \cdot Br \cdot COOH$ , 1:4:1':4'; *monobromophthalic acid*,  $C_{12}H_{11}Br(COOH)_2$  = 4:2:1.

*Dibromoditoly*,  $C_{16}H_{14}Br_2$ , was obtained by treating ditoly dissolved in carbon disulphide with the calculated quantity of bromine. This compound crystallises in beautiful long, almost hair-fine, needles of brilliant lustre, melting at 156°. On oxidation, two brominated compounds of different melting point and composition were obtained (melting points 201° and 170° respectively).

—D. B.

*Constitution of Retene.* E. Bamberger and S. C. Hooker. Ber. 18, 1750.

THAT the hydrocarbon retene is a methylisopropylphenanthrene, and has the constitution—

appears from the following considerations:—

1. It has previously been shown that retenequinone contains the double ketonic group  $CO-CO$ .

2. On oxidation with  $KMnO_4$ , retenequinone is converted into a monobasic acid,  $C_{17}H_{14}O_4$ , which, since it forms a compound with hydroxylamine, must contain a ketonic (CO) group, and hence has the formula  $C_{15}H_{11}O(CO)CO_2H$ ; this ketonic CO group is probably derived by oxidation of the  $CO-CO$  group, as in the formation of diphenylene-ketone from phenanthrenequinone.

3. By further oxidation of the monobasic acid,  $C_{15}H_{11}O(CO)CO_2H$ , by means of  $K_2Cr_2O_7$  and  $H_2SO_4$ , a dibasic acid,  $C_{15}H_8O_6$ , is produced; this also reacts with hydroxylamine, and hence has the formula  $C_{13}H_5O(CO)_2(CO_2H)_2$ ; and since, on dry distillation of the silver-salt, it gives diphenylene-ketone, it must be a dicarboxylic acid of the latter—

4. That the dibasic acid,  $C_{15}H_8O_6$ , has this constitution, is also supported by the fact that on fusion with

KOH it gives a diphenyltricarboxylic acid, and also that it is reduced by sodium-amalgam to a fluorenedicarboxylic acid.

5. From the above it follows that retenequinone must contain the skeleton

and on to this skeleton we have to put  $\text{C}_4$  and  $\text{H}_{16}$ ; this may either be attached in the form of two side-chains or as a ring. The latter constitution, however, is excluded by the formation of the monocarboxylic acid,  $\text{C}_{27}\text{H}_{18}\text{O}_4$ , by limited oxidation, whereas a ring would be sure to give rise to a dicarboxylic acid. The two side-chains may be either a propyl and a methyl group or two ethyl groups. Since the first oxidation product,  $\text{C}_{15}\text{H}_{10}\text{O}(\text{CO})\text{C}_2\text{H}_5$ , contains only one C atom less than retenequinone, the  $\text{CO}_2\text{H}$  group must have been formed by the oxidation of a  $\text{CH}_3$  group, the additional atom of O being probably derived by conversion of the propyl group into an oxypropyl group. Hence this monobasic acid,  $\text{C}_{17}\text{H}_{12}\text{O}_4$ , is an oxyisopropylidiphenyleneketonedicarboxylic acid—

and the retenequinone is methylisopropylphenanthraquinone. That the two side-chains are present in the same benzene nucleus is shown by the fact that the

groups in the ortho position to each other. Hence retenequinone has the constitution—

*Improvements relating to the Distillation of Substances containing Nitrogen, and Apparatus therefor.* H. H. Lake, London. From C. Brisou, Macon. Eng. Pat. 11,449, August 19, 1884.

THIS specification describes an improved apparatus for the production of ammonia and ammonium salts from nitrogenous substances, and which will be understood from the annexed illustration. A (Fig. 2) is a furnace with a return flue  $\text{A}^1$  round the retort B, which has a diaphragm  $\text{B}^1$ , causing its contents to circulate twice the entire length. Above is a heater B, connected to A by two tubes, one of which is  $\text{F}^1$  connected with the perforated tube  $\text{F}^2$ . M is the feed tube from an overhead supply vessel. The heater is filled with the liquid under treatment, which overflows into the retort B. The volatile ammonia is driven off from the liquid in B, and passing through  $\text{F}^2$  is condensed for a time in the liquid in B, but as soon as the temperature is high enough it is again given off and led away to a condensing vessel. The flow of liquor is regulated so as to be continuous, and in passing from the retort is led through a vessel containing lime, and sealing the interior of the retort from the air by means of a hydraulic seal. The

diphenyleneketonedicarboxylic acid produced by the oxidation gives a colouring matter allied to fluorescein on heating with resorcinol, and hence contains its  $\text{CO}_2\text{H}$

remaining part of the non-volatile nitrogenous matter is here decomposed, the vapour following the course already indicated. A continuous stream of lime water

may also be added through the dome E, being held in E', and overflowing through an annular tube E''. In this case the gaseous ammonia escaping from the heater is constrained to pass in the direction of the arrows,

through the milk of lime in E<sup>2</sup> before leaving the apparatus. The patentee claims (1) the apparatus described, (2) the continuous treatment of nitrogenous liquids by such apparatus.—C. C. H.

#### Constitution of Thiophen. J. Thomsen. Ber. 18, 1832.

ABOUT five years ago the author, from his thermochemical researches on the theory of benzene, arrived at the conclusion that the six carbon atoms are combined together by nine single bonds (Ber. 13, 1808). Further investigations on aromatic compounds, such as toluene, mesitylene, aniline, anisole, phenol and phenyl chloride, fully confirm the constitution of benzene, as deduced from the determination of the heat of combustion. Similar investigations on the heat of combustion of thiophen also point to the conclusion that this substance contains no double bonds, the four carbon atoms being combined together by five single bonds.—D. B.

#### Synthesis of Benzene Derivatives from Potassium Carboxide. Nietzki and Benckiser. Ber. 18, 1833.

THE authors have obtained Gmelin's croconic acid,  $C_6H_2O_6$ , from quinone derivatives. In repeating Lerch's experiments on the preparation of trihydrocarboxylic acid, dihydrocarboxylic acid and carboxylic acid from potassium carboxide hexhydroxybenzene, tetrahydroxyquinone and dihydroxydiquinoylbenzene were obtained. The authors conclude that these compounds are identical with the bodies described by Lerch. They have also established the identity of Wilf's rhodizonic acid with their dihydroxydiquinoyl.—D. B.

#### Presence of Paraxylene in Galician Petroleum.

B. Pawlowski. Ber. 18, 1915.

THE author has isolated paraxylene from Galician petroleum (from Kiczany). He found that the crude oil contained about 2 per cent. of aromatic hydrocarbons, consisting mainly of benzene and paraxylene. The presence of the latter was detected by brominating the fraction distilling between 125° and 145°. Crystals of paraxylene bromide,  $C_6H_4(CH_2Br)_2$ , 1:4, were obtained melting at 145°. This is said to be the first time that paraxylene has been detected in petroleum.—D. B.

#### Improvements in the Distillation of Coal Tar and other Hydrocarbon Substances, and in the Apparatus employed therein. H. W. Fenner, Blackheath. Eng. Pat. 13,629, October 15, 1884.

THIS invention consists in the application of stirrers as well as steam for the distillation of coal tar, the object being to effect the distillation with greater economy and rapidity, prevent destruction of the stills and save fuel. The still is provided with a hollow shaft which forms a channel down the centre for the supply of steam, and carries branch pipes for distributing the same. This central pipe, with its branches, is made to rotate by means of suitable gearing.—D. B.

#### An Improved Method of Heating Substances for the Purpose of Distillation. B. Walker, Birmingham. Eng. Pat. 13,650, October 16, 1885.

DISTILLATION is effected by passing through the substance operated upon, a current of heated gas or vapour, which will not injure the distillate, or preferably it may be a portion of the vapour given off by the substance treated.—C. C. H.

### IV.—COLOURING MATTERS AND DYES.

#### The Technology of Mineral Colours. Carl Otto Weber. Chem. Techn. Central. Anzeiger.

##### CHROMIUM COLOURS.

THE most important is chrome yellow, which is also the basis of chromic yellow green, cinnabar green and other similar colours. The preparation of chrome yellow presents difficulties in practice, because products differing in shade and structure, although of uniform chemical composition, are obtained according to modifications of the method of manufacture or nature of materials employed. A special difficulty is the turning of colour, by which a "turned" yellow has a dirty orange yellow colour, which when mixed with barytes gives a yellowish-brown, leather-coloured shade and not a light pure yellow, and other derived colours are similarly affected. The acetate and nitrate of lead are the soluble lead salts generally used. Basic carbonate of lead (white lead) is also much used, the yellows prepared from this material being cheaper, having a large covering capacity and are particularly adapted for ordinary greens; but these have not the smoothness and lightness so much prized in some of the yellows obtained from soluble lead salts. The oxide, sulphate, and chloride of lead have been proposed for the manufacture of chrome yellow, but their treatment would be very tedious and the products obtained only of medium quality. In the manufacture of chrome yellow from acetate of lead and bichromate of potash, different proportions of these materials are given by different authorities, but some of these are obviously wrong where an excess of bichromate is to be used, for every light chrome yellow is liable to turn by the action of chromic acid or a chromate and thereby become of little value. Proportions should be used, whereby the acetate of lead remains in excess, and the reaction should take place in a solution as cold and dilute as possible. In this way a brilliant yellow tint is obtained. For the lighter chrome yellows, lead sulphate is precipitated simultaneously with the chromate by adding sulphuric acid or a soluble sulphate to the solution of the bichromate; these yellows have less tendency to change colour than the pure chromate of lead, if the above precautions are observed. Chrome yellow, precipitated from an excess of a lead acetate solution, by means of potassium bichromate, corresponds to the formula  $PbCrO_4$ . When dried it forms light pieces, which show a conchoidal fracture. A still more voluminous product corresponds to the formula  $PbCrO_4 \cdot PbSO_4$ . The yellow having the composition  $PbCrO_4 \cdot 2PbSO_4$ , is very heavy and shows a smooth fracture. Lightness is often imparted to chrome yellow by the addition of magnesium carbonate. Nitrate of lead offers no advantages over the acetate and is generally more expensive to use. Free nitric acid is more objectionable than free acetic acid, because it may act as a solvent on chrome yellow and liberate free

chromic acid, which is liable to "turn" the yellow. When using lead nitrate it is preferable to neutralise potassium bichromate with soda to avoid the presence of free nitric acid. The yellows mostly in demand are the inferior qualities, prepared by mixing pure chrome yellows with white mineral matters, generally barytes, gypsum and kaolin, usually stirred in with the bichromate solution before adding the lead salt. Barytes injures the colour least, but kaolin has the advantage that it does not increase the weight of the colour so much. Gypsum occupies an intermediate position, it is much more voluminous than barytes and does not injure the colour so much as kaolin, but it is generally used together with barytes. It is not advisable to use this combination, for the reason that the colour on drying forms very hard pieces, which offer difficulties in grinding. Gypsum too, from being more easily acted on by reagents than barytes or kaolin, tends to take part in the reaction by decomposing the potassium bichromate before the addition of the lead salt, and this is objectionable.—G. H. B.

*The Tannins and Derivative Colouring Matters (Artificial).*  
O. N. Witt. Chem. Ind. 1885, 100—105.

THE tannins form a well-marked group of aromatic compounds which, from the circumstances of their occurrence in nature, are destined to attract much attention from those who pursue chemistry as a branch of natural history. The author, in this paper, traces the constitutional connections which have hitherto been established between these compounds and the artificial aromatic colouring matters, and the view he gives has, therefore, an additional technical interest, foreshadowing, moreover, an extended application of the tannins in the future to the production of such compounds. The older classification of the tannins on the basis of their reactions with iron salts has been re-enunciated by Watts as the exact correlative of the constitutional relationship established by his researches—i.e., the tannins giving a green colouration with solutions of the iron salts are all derived from pyrocatechol; those giving a blue reaction are, on the other hand, derivatives of pyrogallol. The typical representatives of the former are the tannin acids of catechu and the oak bark; of the latter the tannin of oak galls; while in the kino of Malabar kino, which has been shown to be a guaiacolate, we have a representative of a group of intermediate compounds, constructed upon a mixed type.

The best-known tannin, or ordinary "tannic acid," is closely related to the trihydric phenol pyrogallol  $C_6H_3(OH)_3$ ,<sup>1, 2, 3</sup> and more directly to gallic acid,  $C_6H_3(OH)_3COOH$ .<sup>4</sup>

Tannin, in solution, in contact with alkalis, absorbs oxygen from the air, and is converted into tannoxylic acid, or into tannomelanolic acid at the boiling temperature. Treated in acetic acid solution with nitroso-compounds, it yields colouring matters, with nitrosodimethylamine, e.g., a violet. By the action of certain acids it is converted into ellagic acid, a carboxyl derivative of a hexa-hydroxy-diphenylketone,  $C_{12}(OH)_6 : CO : C_6(OH)_3(COOH)$ . The constitution of this body, together with its characteristic colour reactions, indicate its probable wide application to the synthetic production of colouring matters, so soon as it can be made commercially available.

The relationship of tannin to gallic acid has been established by the well-known researches of Schill. The conversion of gallic acid by the action of dehydrating agents into rubigalic acid or hexa-hydroxyanthraquinone, is thus expressed by the author:—

By the regulated action of sodium amalgam, Widmann has succeeded in converting rubigalic acid into alizarin, but the result remains for the present of purely theoretical interest. Gallic and benzoic acids treated together with

concentrated sulphuric acid, are condensed to trihydroxyanthraquinone or anthragallol, a very serviceable colouring matter. Gallic acid reacts with nitroso-compounds to form colouring matters, which are the galloxyanins patented by H. Koechlin. These are fixed by means of chrome mordants. The following is an excellent formula for painting in these colours:—

75 gr. wheat starch,  
½ litre galloxyanin paste,  
½ " tragacanth,  
½ " pyroligneous acid 7° B.,  
½ " Turkey-red oil,

are boiled together, stirred till cold, and mixed with ½ litre chromium acetate (20° B.) and 30grm. yellow prussiate. This mixture is printed and steamed in the usual way.

Pyrogallol, the phenol basis of these tannins, is technically interesting from its condensation, with phthalic anhydride, to the well-known colouring matter gallein. From the analogy of its formation, this body was supposed to be a dihydroxy-derivative of fluorescein until the researches of Buschka established for it the following constitutional formula:—

By dehydration with sulphuric acid, gallein is converted into cerulein,  $C_{20}H_8O_6$ , a derivative of phenylanthracene, yielding this hydrocarbon on distillation with zinc dust. The following formula for preparing this colour for printing has been found to give excellent results:—600grms. of the commercial cerulein (paste) are mixed with 320 grms. sodium bisulphite solution at 30° B., the mixture allowed to stand 3 hours, and then intimately mixed with 120grms. chrome acetate (10° B.) and 3kilo. thickening, previously incorporated together. The thickening is composed of the following:—80grms. wheat starch, 80grms. light gum, 400grms. tragacanth (jelly), 800grms. water, 200 olive oil. These are boiled for half an-hour, stirred till cold, and the mixture strained.

The condensation products of pyrogallol with aldehydes, investigated by Bayer, have not yet received any technical application. Another interesting derivative of pyrogallol is the nitro compound obtained by treating the phenol in ethereal solution with nitrous acid; this is converted by reduction into amidopyrogallol, which gives a blue colouring matter on treatment with solution of sodium hydrate. Pyrogallol treated with diazobenzene nitrate yields an orange-yellow colouring matter.

The colour reactions of the second group of tannins, derivatives of pyrocatechol, are, as so far established, much less numerous. The constitutional relationships of these derivatives are also much more difficult of investigation. The catechols are converted by oxidation with chromic acid into brown colouring matters. With nitroso-compounds they yield violet colouring matters, as do also machronin, the tannin and morin, the colouring matter obtained from *morus tinctoria*, and the tannin of the horse chestnut.—C. F. C.

*Pentamethylaminobenzenes.* A. W. Hofmann. Ber. 18, 1821.

THE author gives the following method for the preparation of pentamethylaminobenzenes:—2 parts of methyl iodide are slowly added to 1 part of cumidine, and the reaction is completed on the water bath. On the addition of water, methyl- and dimethyl-cumidine dissolve, and also any unchanged cumidine in the form of hydriodides, and by adding alkali the bases separate out. The mixture boiling between 220° and 230° is again heated with an equal weight of methyl iodide in a closed tube for 8 hours to 240°—250°. The product, a dark-coloured crystalline mass, contains resins, hydrocarbons (chiefly hexamethylbenzene), and pentamethylaminobenzenes, with other bases in the form of hydriodides. The mass is treated with steam, which drives off the hydrocarbons. It is then filtered and saturated with caustic soda to free the bases. A crystalline mass and an oily substance separate, the latter

being dissolved by washing repeatedly with aqueous alcohol. The crystalline compound thus purified is re-dissolved in  $\text{HCl}$  and precipitated with caustic soda, when a solid base separates, which may be re-crystallised from alcohol. The ultimate analysis of the compound and that of the platinum salt correspond to the formula for pentamethylamidobenzene,  $\text{C}_6\text{H}_4\text{N}_2\text{N}^+\text{C}(\text{CH}_3)_5\text{NH}_2\text{M}, \text{pt.} = 151^\circ$  to  $152^\circ$  and b.pt.  $277^\circ$  to  $278^\circ$ , the reaction taking place according to the following equation:—

By the further action of methyl iodide on pentamethylamido benzene, the methylated aniline may be prepared. The dimethylated compound, however, could not be obtained in this way. From this base the author has prepared the corresponding isonitrile by the action of chloroform, and also the nitrile, the latter being characterized by its stability in presence of mineral acids. By the action of  $\text{KNO}_3$  on the anine, pentamethylphenol is obtained in white needles, and by heating the base with  $\text{CS}_2$  the corresponding mustard oil and sulpho-urea may be prepared.—J. B. C.

*Derivatives of Thiodiphenylumine.* N. Fraenkel. Ber.  
18, 1843.

In a previous paper (*Ber.* **17**, 2857) it was shown that, by the introduction of one amido group into thioldiphenylamine, the leneo base of a dye is obtained. The author has continued his investigations and has prepared the following derivatives:—*Benzoylthioldiphenylamine*  $C_6H_5 \cdot CO \cdot N(C_6H_5)_2 \cdot S$ , obtained by heating thioldiphenylamine with an equivalent quantity of benzoyl chloride in a sealed tube at  $100^\circ$ . It crystallises from alcohol in the form of laminae and from glacial acetic acid, benzene or petroleum spirit in flat needles melting at  $167^\circ$ . *Thioldiphenylurethane*,  $S(C_6H_5)_2 \cdot N \cdot CO \cdot OC_2H_5$ , obtained by heating thioldiphenylamine with chloro-carbonic ether and ethyl alcohol to  $100$ – $120^\circ$ . It crystallises in white silky laminae melting at  $109$ – $110^\circ$ . *Thioldiphenylcarbonylchloride*,  $S(C_6H_5)_2 \cdot N \cdot CO \cdot Cl$ , prepared by heating thioldiphenylamine with an excess of carbonylchloride (dissolved in toluene) in a sealed tube at  $100^\circ$ . Crystallises in thick clusters of prisms or needles melting at  $167.5^\circ$ . *Di-thioldiphenylurea*,  $CO(NC_2H_5)_2 \cdot S_2$ , obtained by heating thioldiphenylcarbonyl chloride with thioldiphenylamine (diluted with benzene) in sealed tubes to  $200^\circ$ . It crystallises in fine colourless laminae melting at  $223$ – $225^\circ$ . The author has studied also the action of concentrated sulphuric acid on thioldiphenylamine. A phenolic dye of the formula  $C_{12}H_7NSO_4$  is obtained, called *thionol*. Its constitution appears to be

$$\text{N}(\text{C}_6\text{H}_5)_2\text{SO}(\text{OH}).$$

—D. B.

## V.—TEXTILES : COTTON, WOOL, SILK, Etc.

*Improved Process and Solution or Liquid for treating Textile and other Materials, whereby they may be rendered Waterproof.* Alfred Julius Boulton. From Otto Hiller. Eng. Pat. 14,725, November 7, 1884.

THE solution is prepared by adding a solution of acetate of lead to one of sulphate of alumina in such proportion that a slight excess of sulphate of alumina remains in solution. The precipitate of sulphate of lead is removed by filtration, and to the solution of acetate of alumina, a solution of albumen is added and, if necessary, the liquid again filtered. The material to be rendered waterproof is saturated with this solution, dried and passed through hot rollers to coagulate the albumen. Certain precautions are necessary, such, for example, as the employment of pure chemicals.—E. J. B.

*The Manufacture and Application of a Novel Product Impervious to Air and Water.* Ernest de Pass. From Albert Lèbre. Eng. Pat. 15,075, November 15, 1884.

IN working out a process for waterproofing fabrics, patented in 1883, November 5, No. 5242, it was discovered that a combination is effected between cotton or similar substances and the waterproofing material

employed. The compound so formed has been called by the inventor "Hydrofuge Cotton." It has many useful industrial applications.—E. J. B.

*Improvements in the Preparation and Utilisation of Fruit Fibre for Textile Purposes.* William Phillips Thompson. From George Henri Béraud. Eng. Pat. 15,877, December 3, 1884.

THE preparation of the raw material is effected by scutching and carding the peat by machines similar to those used in the preparation of other fibres; the dark colour of the material may be got rid of by the use of bleaching agents in the usual way.—E. J. B.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Artificial Alizarin in Wool Dyeing.* The St. Denis Dyes and Chemical Products Company. Chem. Zeit. 1885, 926, 927.

THE artificial product dissolves in the bath just as the wool takes it up, so that the operation requires no more time than is needed by the dye as generally used. By merely changing the mordant and its relative amount a large number of shades can be produced. Thus with aluminium salts can be obtained shades from delicate rose to deep red; with chromium salts from light wine colour to dark chestnut-brown; with iron salts from light lilac to dark violet; with manganous salts from a greyish blue to dark slate; with nickel salts from greyish lilac to bluish garnet, with tin salts from rose to deep red, etc. Fastic and carnelin dye with the same mordants and add to the number of colours which can be attained by the help of alizarin. Dyeing by means of alizarin is effected in two stages; first, the mordanting, and then the dyeing proper. The former is done at a boiling temperature and takes from 1—1½ hours. After being washed in running water the dyeing proper follows.

—J. T.

*Improvements in Machinery for Printing in Colours.* A Grafton, London. Eng. Pat. 14,876, November 11, 1881.

THE inventor describes with great fulness of mechanical detail a polychromatic printing machine which he has devised, "capable of printing on large surfaces and free from any irregularities of motion which would cause imperfect impressions."—J. H. H.

*Improvements in Bleaching and Apparatus therefor.*  
J. H. Johnson. From E. Hermite, Paris. Eng. Pat.  
13,929, October 21, 1881.

This invention relates to an improved process and apparatus for bleaching yarn, textile fabrics, paper pulp, etc., by means of the electrolytic decomposition of magnesium or calcium chloride—preferably the former. The reactions which ensue when a solution of  $MgCl_2$  is submitted to electrolysis are extremely complex, and the inventor gives several equations—though unfortunately he uses the old notation—showing that chlorates, chlorites and hypochlorites are formed and that the action is continuous,  $MgCl_2$  being the final product. Hence the same solution can be used an indefinite number of times. A solution of  $MgCl_2$  of sp. gr. 1.125 (25° T.) gives the best results; with  $CaCl_2$  a sp. gr. of 1.191 (38° T.) is required. The inventor states that he has shown experimentally that, in order to bleach linen thread, the quantity of chlorine required is only about one-ninth of that required by the ordinary bleaching powder method. The negative electrodes consist of zinc plates bolted together and soldered to copper rods which are connected with the main conductors, and insulated by means of varnish from contact with the liquor. The positive electrodes are platinum plates sunk into wooden frames and similarly soldered to copper conducting rods. In the figure annexed C C are the zinc plates; D D the platinum plates, and e e and d d the copper conducting rods, while through the holes

let pass the bolts joining the zinc plates. Various methods of applying the process to cotton goods, yarn and paper pulp are described; in the case of the last-mentioned the electrolysed solution must be run off as soon as the bleaching is completed. The specific resist-

the slag will contain the phosphorus from the metal as an alkaline phosphate, more or less soluble in water. The slag may be subsequently fused with alkaline carbonate, hydrate or sulphate, to render the whole of the phosphoric acid soluble in water.—S. H.

ance of a solution of  $MgCl_2$  of sp. gr. 1.125 at  $30^\circ C$ . is 6.1 ohms, and the polarisation in open circuit 2.13 volts. The inventor claims that the most delicate textiles are not in the least injured by the use of his process of bleaching.—J. H. H.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Cause of Decrepitation in Samples of so-called Explosive Pyrites.* B. Blount. J. Chem. Soc. August, 1885, 593.

THE author found that these decrepitations were due to the presence of confined carbonic dioxide and water, but the  $CO_2$  and  $H_2O$  did not occur in any definite ratio to each other, one sample being quite free from moisture. The particular pyrites examined was copper pyrites from the Cosheen Copper Mine on Scull Harbour, County Cork.—F. L. T.

*Improvements in the Manufacture of Salt from Brine, and in Apparatus therefor.* H. Whitehead and R. Hodgson, Sandbach. Eng. Pat. 14,533, Nov. 4, 1884.

THIS invention consists in a greatly improved system of evaporating, and in apparatus for carrying it into effect. The liquor to be boiled down is alternately heated to the boiling point and then allowed to cool, the crystals being meanwhile fished out. The cold mother-liquor is again heated, cooled, and so forth, until all is evaporated. In actual practice the process becomes continuous by dividing the pan into a series of troughs, communicating alternately at each end, sending the hot liquor in at one end and pumping the cool out at the other for reheating. The apparatus consists of two cylinders containing a series of pipes through which the brine is made to pass by means of a pump. The upper cylinder is supplied with steam from the boiler, the lower cylinder being heated by the exhaust steam of the pump. The brine in passing through the pipes becomes heated to its boiling point, then flows into a pan, where it cools down and deposits salt, and afterwards flows continually through an overflow into a tank, from which the pump passes it into the pipes and into the pan as before. The tank is automatically supplied with new brine. The salt is drawn from the pan by a mechanical scraper. As no heating of the pan is required, it can be built of cement, and consequently the wear and tear incident on heating brine-pans by firing below, is avoided.—S. H.

*Improvements in the Manufacture of Alkaline Phosphates.* P. M. Justice, London. From L. E. Thomas, Paris. Eng. Pat. 14,549, November 4, 1884.

AN intimate mixture of an alkaline chloride and caustic alkali is exposed to the action of molten phosphoric iron in a converter, preferably having a basic (Thomas & Gilchrist) or neutral lining. Carbonate of soda or potash, or magnesia or oxide of iron are added to the mixture to diminish its volatility. At the end of the operation

*Improvements in the Treatment of Sulphate of Iron.* S. Callard, Carmarthen. Eng. Pat. 15,393, November 22, 1884.

THIS invention relates to improvements in the drying of sulphate of iron previous to its being placed in the muffle, as described in Letters Patent 5930, April 4, 1884, for "Improvements in the destructive distillation of sulphate of iron, and in the obtaining therefrom of sulphurous acid and red oxide of iron." For the purposes of this invention the sulphate of iron is heated in iron pans along with a certain amount of sulphuric acid, which prevents the formation of scale and brings the whole charge in a pulverised condition when dry.—S. H.

*Improvements in Treating Salt, etc.* A. Collingridge, London. From V. Cornet and A. Jones, Paris. Eng. Pat. 5706, May 9, 1885.

UNSUITED for abstracting.—C. C. H.

*Obtaining Liquid Anhydrous Sulphurous Acid from Furnace and other Gases.* E. Haenisch and M. Schroeder, Oberhausen, Prussia. Eng. Pat. 6405, May 26, 1885.

THE object of this invention is to obtain anhydrous sulphurous acid from gases containing only a small percentage of sulphur dioxide. The process may be divided into three distinct stages. 1. The production of watery sulphurous acid solutions by bringing furnace gases in contact with a stream of cold water. 2. The production of pure sulphur dioxide by heating the sulphurous acid solution. 3. The condensation of sulphur dioxide by compression or refrigeration. The gases from the roasting kiln pass through a pipe into an absorbing tower, charged with coke, where they are met by a copious spray of cold water. The solution thus formed flows into a series of closed pans, made of sheet lead, to which heat is applied. The sulphur dioxide evolved passes into a cooling worm, and then for removing the last traces of water into a vessel charged with pieces of calcium chloride, and thence to a compression pump. The water from the pans is deprived of the last traces of sulphurous acid by allowing it to pass through a tower filled with lead-wire network, where it meets steam at the bottom. The pressure within the apparatus is regulated by means of a taffeta bag, the working of the pump being regulated by the dimensions it may assume for the time being. The gases compressed by the pump are cooled by the worm and condensed in the receiver, whence the liquid sulphurous acid may be drawn off for use.—S. H.

*Improvements in Decarbonating the Carbonates of Strontia and Baryta, and in Apparatus therefor.* Abel and Imray, London. From H. Leplay, Paris. Eng. Pat. 8541, July 14, 1885.

THE invention refers to a former specification, No. 9765, July 4, 1884, where the decomposition of the carbonates

of strontia and baryta by means of superheated steam was described. The mode of proceeding has now undergone several alterations. The steam is not brought in contact with the carbonate until the latter has been raised to a sufficiently high temperature to cause its immediate decomposition. For this purpose the kiln is heated by producer gas, containing carburetted hydrogen, which, on entering into combustion, produces steam heated to a high degree, which assists in the decomposition of the carbonate. In order to obviate fluctuations in the decomposing kiln, the carbonate previous to entering the furnace is dried in a muffle, heated by the hot waste gases of the kiln. Baryta treated in this manner is reduced to a molten mass, which offers an insufficient surface to the action of the steam. The inventor, therefore, introduces into the lower part of the kiln basic aluminous or magnesian perforated blocks, which are not attacked by the molten monohydrate, and which cause the latter to flow downward in a subdivided state while subject to the action of steam.—S. H.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

*Improvements in Machines for Making Pottery, Glassware, and Articles of all kinds, from Soft Plastic Materials which are capable of being moulded.* C. C. Thompson, of East Liverpool, Columbiana County, Ohio, U.S.A. Eng. Pat. 7367, June 30, 1885.

The object of this invention is to provide a machine for forming articles having both straight and curved surfaces from clay, glass, paper pulp, and similar plastic materials—which are capable of being moulded—and to so construct the parts to which the shaping tools are secured that the tools will have both a reciprocating and downward and upward lateral movement in forming the article which is being made, for the purpose of preventing the material which is being shaped from being injured at its bottom by the shaping tools as they are drawn backwards after having been moved laterally for the purpose of forming the swell or concave-convex in the article. Detail drawings are furnished.—T.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

*An Improved Process for the Manufacture of Asphalt.* H. Kettman, Brunswick. Eng. Pat. 12,425, September 15, 1884.

THE methods ordinarily used for the manufacture of asphalt do not result in the production of a sound and homogenous material, because the bituminous bodies used do not become so intimately incorporated with the limestone, etc., as they should do. The author proceeds as follows:—Crude bitumen is heated with hydrocarbon oils; the clayey matter is deposited. The quantity of oil used is such that at a temperature of 17° C. to 33° C. the bitumen should be capable of being drawn into threads. Limestone or asphalt stone is finely powdered and mixed with about 40 per cent. of water, forming a thin cream; 15 per cent. of the bitumen at a temperature of 70° C. is then added and the whole well incorporated. The suspension of the stone in water provides a condition under which it may be properly and thoroughly coated with bitumen. The temperature is raised to such a point that the water is finally expelled. The liquid mass is then cast into blocks and is ready for use.—C. C. H.

*The Manufacture of Waterproof Cement.* W. Smith, Dublin. Eng. Pat. 13,355, October 9, 1884.

EQUAL weights of finely-powdered limestone and pitch are intimately mixed. The resulting product may be used as a cement for binding together building materials or as a waterproofing material in building works. It may also be used in combination with other materials for the manufacture of waterproofing materials.—C. C. H.

*A New or Improved Fibrous Fireproof and Waterproof Composition for Constructive, Decorative, and other Purposes.* W. Millar and C. F. Nichols, London. Eng. Pat. 2927, March 5, 1885.

THIS material is to be applied for decorative purposes and as a substitute for papier maché, wood, etc. A mixture of powdered brickdust, pumice stone, slag wool and Portland cement is moistened with an aqueous solution of carbonate of soda and ammonia, caustic soda, chloride of magnesium or bitter water: to impart strength or flexibility, the plastic mass is applied to wire work or perforated metal, or incorporated with tow and rendered fireproof by immersion in a solution of borax, and if hardness is required, steeped in a solution of calcium chloride and a subsequent bath of silicate of soda, and finally washed in bichromate of potash.—C. C. H.

*An Improved Metallic Compound for Flooring, Paving, and other Purposes.* C. A. Wilkes and W. Millar, London. Eng. Pat. 7148, June 11, 1885.

THE improved compound when used as flooring does not become slippery or soften in hot weather, and sets rapidly. Blast furnace slag is broken to a fine powder and washed; if a striking colour be desired the product is mixed with oxides of iron. To three parts of slag one part of hydraulic cement is added and sufficient water, which contains in every gallon one part of bitter water, 5 per cent. of carbonate of soda, 2.5 per cent. of carbonate of ammonia, a little potash, and if rapid hardening is desired 1 oz. of calcium sulphate is added to every gallon of water.—C. C. H.

## X.—METALLURGY, MINING, Etc.

*The Co-operation of Water in the Slow Oxidation of Zinc, Lead, Iron, and Hydrogenised Palladium.* M. Traube. Ber. 18, 1877.

THAT water assists the oxidation of the non-precious metals by air is well known, but the part played by the water has not been studied, it being taken for granted that the metals unite directly with the oxygen of the air, forming oxides. The author was the first to show that the phenomena accompanying this oxidation can only be explained by the splitting up of the water molecule (Ber. 15, 663).

If metals unite with free oxygen, oxides will be produced; but should hydroxides be produced, it would be a proof that water enters into the reaction. The author finds that in the case of zinc, lead, and iron, hydroxides are produced. Further, if the water took no part in the reaction, the oxidation of these metals should take place equally well with any other liquid in presence of air—e.g., absolute alcohol. But on trying, there was found to be no oxidation; alcohol diluted with water, however, did cause oxidation.

The hydrogen occluded by palladium possesses in a high degree the property of combining with the atmospheric oxygen at the ordinary temperature, and on exposing a piece of palladium foil highly charged with hydrogen, to the air, its hydrogen combines with the atmospheric oxygen so rapidly that the foil becomes red-hot. It was found that hydrogenised palladium when covered with absolute alcohol and exposed to air did absorb oxygen, but as it was in this case impossible to be certain that every trace of water was absent on starting the experiment, and the product of oxidation also being water, it is easy to see that a trace of water in starting would be capable in a short time of producing a large quantity. The author found that hydrogenised palladium placed under strong sulphuric acid did not absorb oxygen, but that it did so on diluting the acid. He obtained a similar result on using a syrupy solution of pentoxide of phosphorus as his drying agent. The author has found that neither zinc, lead, iron, nor hydrogenised palladium will act on water free from air at the ordinary temperature. The action of zinc on water and oxygen can be represented:  $\text{Zn} + 2\text{OH} + \text{O}_2 = \text{Zn}(\text{OH})_2 + \text{H}_2\text{O}_2$ , and confirming this equation, it is found that hydrogen peroxide is produced. This also shows the

true nature of peroxide of hydrogen, which is to be regarded not as a higher oxide of hydrogen, nor as an oxidation product of water, but as a combination of an oxygen molecule. Lead and hydrogenised palladium also produce hydrogen peroxide on oxidation. The hydrogen peroxide produced in this manner cannot occur in large quantities, because the metals and the hydrogen are capable of reducing it again.

The author concludes that as nascent oxygen destroys hydrogen peroxide, the presence of hydrogen peroxide in these experiments shows that no nascent oxygen could have been present.—F. L. T.

*Improvements in Metallurgy.* Dingl. Polyt. J. 256, 506-573.

**Crucible Steel.** F. C. G. Müller.—For refined steel the crucible process is indispensable. In an Austrian establishment the graphite used for crucible making in the following experiment consisted of carbon, 75 per cent.; silica, 13; alumina, 8; iron oxide, 1.8; lime, 0.2; and water, 2 per cent. The clay used contained silica, 50.1 per cent.; alumina, 33.6; iron oxide, 2.8; potash, 3.2; magnesia, 0.5; and water, 10.1 per cent. The crucibles were charged with 20 to 30 kilos., and were heated in a Siemens furnace, with others, in the ordinary course of work; hard steel fusions were heated five hours; soft steel, six hours. In a crucible made of three parts graphite, and 3.25 parts clay, the following fusions were made:—

	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)
C....	3.593	3.709	3.773	3.636	0.939	1.193	1.268	0.048	0.251	0.350

Si...	0.075	0.378	0.765	1.069	0.021	0.358	0.628	0.021	0.081	0.257
P....	—	—	—	—	0.012	—	—	0.041	—	—

Number (1) is soft Styrian pig iron; (2) is the same once melted in the crucible; (3) is twice melted, and (4) is three times melted. Number (5) is raw refinery steel; (6) is the same once melted, and (7) is twice melted. Number (8) is refinery bar iron; (9) is the same once melted, and (10) is twice melted. The ingot (9) was full of blow-holes, whilst that of (10) was quite sound. In the two following experiments—i.e., analyses (11)-(16), inclusive—with crucibles of five parts graphite to one part clay, the upper part of the crucibles became perforated, so that furnace-gases had access to the contents. Later, two new experiments were made, in which only the lower part of the crucible was made of five parts of graphite to one of clay, the upper part being of the ordinary mixture—1:1. These pots remained sound.

	(11)	(12)	(13)	(14)	(15)	(16)	(17)	(18)	(19)	(20)	(21)	(22)	(23)	(24)	(25)	(26)	(27)	(28)

Mn..	0.211	—	0.192	0.111	—	0.091	0.110	0.563	0.738	—	—	—	0.179	—	0.111	0.093	—	0.101
Si..	0.031	0.313	0.622	traces	0.290	0.621	0.019	0.203	0.350	0.023	0.302	0.658	0.023	0.330	0.600	0.019	0.202	0.393

Number (11) is raw refinery steel; (12) is the same once melted; (13) the same twice melted. The crucible, as remarked above, burnt through in its upper part. Number (14) is refinery bar iron; (15) is the same once melted, and (16) twice melted. Ingot (15) was porous, whilst (16) was sound. The crucible burnt through above. Number (17) is raw refinery steel; (18) is the same once melted, and (19) the same twice melted. The crucible remained sound, as remarked above; its upper part being composed of one part graphite to one part clay. With (18) and (19), one per cent. of manganese oxide was placed in the crucible with each charge. Number (20) is refinery bar iron; (21) the same once fused, and (22) twice fused. As in the previous experi-

ment, the crucible remained sound. Ingot (21) was blown; (22) was sound. Number (23) is raw refinery steel; (24) the same fused in a new English plumbago pot; (25) the same twice fused. Number (26) is refinery bar iron; (27) is the same once fused in a once-used English plumbago crucible; (28) the same twice fused. Both ingots were blown.

In graphite crucibles of the ordinary make, as well as of those richer in graphite, both hard and soft steels take up about 0.3 per cent. of silicon. In crucibles of the former character, about 0.2 per cent. of carbon is taken up by the steel, whilst in the more graphitic crucibles 0.45 per cent. of carbon is absorbed at a tool-steel heat, and 0.6 per cent. at a scythe-heat. The manganese is unaffected. Manganese is reduced from oxide added to the charge, and the amount of silicon is at the same time reduced. Only the carbon is attacked when furnace gases have access to the charge. The silica present in graphite appears to be more easily reduced than that in the clay. In clay pots, practically no silicon is absorbed by the steel.

**Gases in Steel.** Müller thinks that the gases cannot be expelled by any purely physical process. He states that Wasm fused some Thomas-steel in a clay pot without any admixture. After three hours' heating, on casting, the ingot boiled up much more than the original metal. The metal before melting contained: Carbon, 0.015 per cent.; silicon, 0.011; phosphorus, 0.023. After melting it contained: Carbon, 0.020; silicon, 0.023; phosphorus, 0.034.

**Tungsten-Iron Alloy.** L. Schneider.—An alloy of specific gravity 9.306 at 17° contained: Iron, 68.36 per cent.; tungsten, 28.18; manganese, 0.99; cobalt and nickel, traces; silicon, 0.23; phosphorus, 0.01; sulphur, traces; carbon, 1.88. On boiling with hydrochloric acid a metallic powder was obtained, which could be easily separated into two portions by means of a magnet, whilst only traces of tungsten were dissolved. The non-magnetic portion, composing about ninety per cent. of the whole, consisted of light-grey, well-formed octahedra, hard enough to scratch glass, but brittle enough to be ground in an agate mortar. The amount of iron varied between twenty-four and thirty-one per cent., and the carbon between 1.4 and 1.6 per cent. The magnetic portion was dark-grey, metallic, and, under the microscope, had a frothy appearance. It contained: Iron, 68.1 per cent.; tungsten, 27.7; and carbon, 4.1.

Tungsten-steel of the following composition: Iron, 55.00 per cent.; tungsten, 11.03; manganese, 1.49; silicon, 0.26; phosphorus, 0.01; carbon, 2.15; left 13.1 per cent. of a fine non-magnetic powder on being heated with hydrochloric acid. This powder contained: Iron, 22 per cent.; carbon, 1.1; thus agreeing in composition with the crystalline powder above. On the other hand, soft steel containing tungsten, when treated with dilute hydrochloric acid (1:8), leaves only traces undissolved

of tungsten containing iron. Carbon, silicon, phosphorus, etc., harden steel; tungsten acts similarly, but the former combine with the iron, whilst the latter remains uncombined, consequently a considerable amount of tungsten is necessary to produce a hard steel. Such a steel resists atmospheric corrosion, and damascenes beautifully, owing to the tungsten present.

**Copper Refining.**—W. Braun (Ger. Pat. No. 31276, May 27, 1884) proposes to pass gaseous hydrochloric acid through molten copper, with exclusion of air as much as possible. The red oxide is volatilised as chloride, and all other metals present as oxides, and all metals capable of decomposing hydrochloric acid are also removed. Very tough, compact copper results,

which has a high electric conductivity. The copper can be cast solid in moulds filled with an indifferent gas.

*Oxygen in Metals and Alloys.* A. Ledebur.—This should always be determined by ignition in hydrogen, as a portion is frequently present as oxide. The following amounts of oxygen were found in the various metals and alloys given: Commercial copper, 0.227 per cent.; sheet copper, 0.124; compact copper fused under common salt, 0.092; cast bronze with four per cent. tin, Royal Gun Works, Spandau, 0.070; gun bronze with ten per cent. tin, from the same works, 0.051; ancient bell metal, containing copper, 72.5 per cent.; tin, 23.7; lead, 1.8; the oxygen was 0.126 per cent.; manganese bronze from Spandau, with manganese 0.14 per cent.; iron, 1.53; tin, 5.86 per cent.; the oxygen was 0.036; phosphor bronze from the same, phosphorus, 0.004 per cent.; oxygen, 0.038; Berlin cast brass, 0.033; Vienna cast brass for sheet, 0.015; cast nickel from Pfannestell, brittle, unmaluable, 0.304; malleable nickel from the same (without magnesium addition) in sheet, 0.084; Fleitmann's sheet-nickel (with magnesium addition) from Iserlohn, 0.095; cast German silver, 0.061.—J. T.

*Slow Oxidation of Copper in Presence of Dilute Sulphuric Acid or Solution of Ammonium Carbonate.* M. Traube. Ber. 18, 1887.

The author finds that copper is not acted on by water, either in presence or absence of air. When, however, it is in contact with dilute sulphuric acid in presence of air, or of a solution of ammonium carbonate in presence of air, it is dissolved with simultaneous production of hydrogen peroxide:—

The hydrogen peroxide does not occur in large quantities, because it is again destroyed by a secondary reaction:—

Copper by itself in absence of air is unable to decompose either dilute sulphuric acid or a solution of ammonium carbonate.—F. L. T.

*Influence of Silicon on the Properties of Cast-iron.* Thomas Turner. J. Chem. Soc. 1885, 577.

AUTHORITIES differ as to the influence of silicon on cast-iron, the general opinion being that it is injurious. The

author shows that under certain circumstances it slightly increases the tenacity of cast-iron.

TABLE A.—Summary of Tensile Tests (by Professor Kennedy).

U. C. L. Test Numbers.	Silicon per cent.	Breaking Load per square inch.		Modulus of Elasticity.

The author made "pure cast-iron," and melted it with varying quantities of silicon iron, with a view to obtaining the quantities of silicon in the second column of table A. The mechanical tests were performed by Prof. A. B. W. Kennedy, at University College, London, and the results are in Table A. Table B gives the check analyses of the samples after the mechanical testing. This table also confirms the fact first noticed by Sefstrom, and mentioned by Percy, that in cast-iron which contains much silicon, the carbon chiefly occurs in the graphitic state.—F. L. T.

*Blast Furnace Working.* H. v. Jüptner. Chem. Zeit. 1885, 888—890.

The data obtained from a week's working of a charcoal blast furnace, were as follows: Ore charged, 249,600 kilos.; iron washed from slag, 6000 kilos.; limestone, 26,100 kilos.; charcoal, 106,480 kilos. There were produced: pig iron, 114,600 kilos.; slag, 64,600 kilos.; fine dust (dry), 827.5 kilos.; iron washed from slag, 6000 kilos. Average temperature of the blast = 350° C. Blast pressure (average) 60 mm. water; diameter of tuyeres, 55 mm.; mean temperature of waste gases, 127° C.; average moisture in blast, 0.87 per cent. by weight; mean temperature of the air, 17° C.; mean barometric height,

710mm. The materials given above had the following composition:—

	Ore.	Lime-stone	Slag.	Flue Dust.	Char-coal.

*Ferro-Chromium Alloys.* L. Schneider. Chem. Zeit. 1885, 924–925.

AN alloy containing about 50 per cent. chromium dissolves at first, when warmed with hydrochloric acid, with evolution of gas. But the action is soon stopped by a coating of oily hydrocarbon which collects on the metallic particles. This hydrocarbon is formed in considerable quantity. On removing mechanically the crystalline powder obtained from the pieces of alloy, and heating, or treating with alcohol and ether to get rid of the hydrocarbon, a large portion of this can be dissolved, and in this way alloys with 66 per cent. of chromium may be dissolved. This diffinitely soluble alloy consists of minute crystalline needles. It may also be obtained from ferro-chromium by treating with copper chloride, then with caustic alkali, alcohol, ether, and finally igniting in hydrogen. The crystals contain—Chromium, 66·2; iron, 24·9; carbon, 8·5; nearly corresponding to the formula,  $\text{Fe}_4\text{CCr}_{12}\text{C}_4$ .—J. T.

*The Use of Explosives in Mines.* Chem. Zeit. 9, 1088.

THE following notice has been issued by the authorities of the Cologne Mining Association (Bergwerksverein):—In all workings where fire-damp occurs, blasting with gunpowder and similar slowly-exploding agents is prohibited, not only in the coal measures themselves, but also in the adjoining rock, only the use of dynamite and quickly-exploding agents like dynamite, equally inoffensive as regards coal dust, being permitted. But, blasting with dynamite is not even permitted in those parts of the workings where such accumulations of fire-damp may under ordinary circumstances collect, that the burning of the safety lamp is sensibly affected (3 per cent.).—G. H. B.

*Treatment of Complex Metallic Ores or Solutions.* G. I. J. Wells, Liverpool. Eng. Pat. 12,317, September 12, 1884.

THE author claims the fractional precipitation and separation successively of the metals contained in complex metallic solutions, by means of decomposable sulphides added in such successive portions as shall be necessary to separate from their solutions, and from each other, the metals—copper, lead, zinc and iron. The complex solution obtained from the drainage of alkali waste is suitable as a precipitant.—J. T.

*Improvements in Apparatus for the Amalgamation of Gold and Silver.* George Washington Moon, Regent Street, Middlesex. Eng. Pat. 12,930, September 29, 1884.

By means of an intermittent rotary motion in a vertical plane, the mercury is forced round an oval curve, into the top of which the ore is introduced. Two or more of these curves may be arranged in series for the more efficient amalgamation of the ore. Any flour of mercury which might pass away is caught and retained in an egg-shaped cavity, over which the tailings pass before leaving the machine. Between the curve and this cavity movable amalgamated copper plates are placed.

—W. G. M.

*Coating Vessels of Copper or Copper Alloys with Lead.* J. S. McDougall, Chadderton. Eng. Pat. 15,800, December 1, 1884.

THE surface of copper, or copper alloy, to be coated, is cleaned, and is coated with zinc chloride (or its equivalent in this application), and afterwards a coating of lead of any thickness is attached by means of heat applied in any suitable manner.—J. T.

*Improvements in the Reduction of Iron or Zinc Ores.* W. R. Lake, London. From G. M. Westman, Stockholm, Sweden. Eng. Pat. 15,561, December 2, 1884.

THE apparatus consists of three furnaces, two heat regenerators, two air-heating chambers, suitable connecting pipes, and four valves. The furnaces have closed mouths, shafts and hearths. Two powerful blowing engines are provided, one for the gases and the other for the blast. In working zinc ores, the central furnace is charged with briquettes of calcined zinc ore and coal powder. The outer furnaces are filled with fuel only, are used alternately as condensers of zinc vapour, and as gas generators respectively. In working iron ores, the central furnace is filled with fuel only, whilst the outer furnaces are filled with fuel, ore, and fluxes as in an ordinary blast furnace. While the ore is reduced in the one outer furnace, the ore already reduced is melted in the other outer furnace. The central furnace is used to regenerate or again carburise the gases arriving from the reducing furnace.—J. T.

*Smelting Sulphide of Antimony.* N. C. Cookson, Newcastle-on-Tyne. Eng. Pat. 3386, March 16, 1885.

THE reduction of antimony sulphide is to be effected by pouring over it molten iron. The sulphide is placed in

a ladle lined with refractory material, and the molten iron is poured over it, thus avoiding the use of crucibles. After the decomposition has been thus effected, the contents of the vessel are poured into a receiver, and after cooling the products separated in the usual way.—J. T.

*Manufacture of Iron Sponge, Iron, and Steel.* W. R. Lake, London. From C. J. Eames, New York, U.S.A. Eng. Pat. 6429, May 26, 1885.

IRON ore is intermingled with an impure graphite, known as "graphitic carbon," and after being heated by waste gases from the furnace, it is more strongly heated on the hearth of a reverberatory furnace. This furnace has, by preference, an improved hearth formed of friable graphitic lumps. After the ore is reduced on this hearth it is passed over to a second hearth nearer to the fire, and the spongy mass is there balled up.—J. T.

*Improvements in the Manufacture of Iron Sponge, Iron, and Steel.* W. R. Lake. From C. J. Eames, New York. Eng. Pat. 6430, May 26, 1885.

CLAIMS to make wrought iron direct from ores by melting the ores in a furnace having its hearth composed of a mixture of graphite, pulverised fire-brick, and coal-tar or molasses, or their equivalents. The remaining claims are substantially covered by the preceding specification.—J. T.

*Improvements in the Manufacture of Iron Sponge, Iron, and Steel.* W. R. Lake. From C. J. Eames, New York. Eng. Pat. 6431, May 26, 1885.

THE inventor proposes the use of a stiff paste made from pulverised graphite, and an adhesive carbonaceous cement, such as tar or molasses, which paste can be readily applied as an adhesive covering to the ore.—J. T.

*Improvements in the Thomas-Gilchrist Process.* W. P. Thompson, London. From B. Osann, Potsdam, Prussia. Eng. Pat. 8392, July 11, 1885.

BY fusing a mixture of sodium or potassium carbonate with iron sesquioxide or manganese sesquioxide, an anhydrous refractory compound will be obtained which, when treated with water, gives a solution of caustic soda or caustic potash with separation of iron or manganese sesquioxide. If, instead of adding the usual lime flux to the Thomas converter, the above mixture be used, caustic alkalis can thus be cheaply produced, and the phosphoric, chromic, vanadic, or other acids formed in the Thomas-slag, are rendered easily soluble in water.—J. T.

*Obtaining Aluminium and other Metals from their Ores.* W. P. Thompson, London. From E. H. Cowles and A. H. Cowles, Cleveland, Cuyahoga Co., Ohio, U.S.A. Eng. Pat. 9781, August 18, 1885.

THE object of this invention is the reduction of aluminium from its ores by electricity and its production in a pure state or as an alloy with other metals. In a prior application for Letters Patent 6994, June 9, 1885, a process of smelting ores and reducing the salts of refractory metals by means of electricity is described, consisting in the use of pulverised carbon made incandescent by the passage of an electric current, and in carrying out the present invention the said process is preferably used. Ores of alumina are reduced in the said furnace by mixing them with granular carbon and passing an electric current through the mixture; but the product thereby obtained contains a considerable percentage of carbon which is taken up both chemically and mechanically by the aluminium. If, however, the ore of aluminium be reduced in company with tin, copper, manganese or other metal which will alloy with the aluminium, very little if any of the carbon is taken up. The alloying metal may be subsequently separated from the aluminium by amalgamation, lixiviation, or equivalent process, leaving the aluminium in the form of an amorphous powder. The method consists in mixing with the broken charcoal

pieces of the metal which is to constitute the base of the alloy, whereby it is melted by the incandescent carbon and takes up the other metal, whatever it may be, that is being reduced.—J. T.

## XL.—FATS, OILS, AND SOAP MANUFACTURE.

*Process for Converting Petroleum and similar Hydrocarbons into Acids, Soaps, and Compounds analogous in constitution to Resins and Ethers.* J. Murray. From Dr. Eugen Schaal, of Stuttgart. Eng. Pat. 12,806, September 25, 1884.

PETROLEUM and hydrocarbons resulting from the dry distillation of coal, shale, peat, etc., are heated with caustic alkalis, their carbonates, alkaline earths, or other substances having an alkaline reaction, with or without pressure, in a current of air or oxygen; the hydrocarbons are said to be converted into acids, and to form soaps. These are removed, and decomposed with mineral acid, the resulting acids being separated by distillation, fractional precipitation, or extraction with benzene or petroleum. Other oxidising agents are also employed, such as chloride of lime, at from 130° to 200° C., after which the lime is removed by hydrochloric acid, and the remaining oil compound (after separation of the acids) is treated with about 50% caustic soda at from 200° to 300° C. In some cases nitric acid is employed in the gaseous form together with a strong current of air, at about 100° C. Super-oxidation, which sometimes occurs with the liquid acids, apparently by formation of dry acids, can be brought back again by treatment with zinc powder. The separate fractions of the acid mixtures resulting from oxidation of the hydrocarbons may be used partly for the production of ether-like bodies, partly for soaps, and partly may be themselves used as such. The most volatile acids give, with methyl, ethyl, butyl, and amyl alcohols, useful aromatic ethers suitable for perfumes. The acids of higher constitution are very nearly related to oleic acid.—W. L. C.

*Improvements in Apparatus for Solidifying Paraffin in Oils.* F. N. Mackay and W. Baxter. Eng. Pat. 14,114, October 25, 1884.

THE oil is cooled in tanks surrounded with a refrigerating medium, and these tanks are provided with scrapers and agitators worked from an overhead shaft, and used in such a manner as will best ensure (1) the contents being mixed while cooling is being done, and (2) the cooling surfaces being continually freed from frozen paraffin. The whole mass is gradually brought down nearly to the temperature of the refrigerating medium, after which the discharge-ways are opened, and the contents of the tanks are allowed to flow to the press pumps. Drawings are given.—W. L. C.

*Improvements in the Preparation of Oils used for Lubricating Woods preparatory to Spinning.* C. Rumble and F. Sear. Eng. Pat. 15,031, November 14, 1884.

TO avoid the tendency to spontaneous heating in such oils, some metallic or ammonium salt or salts of fatty or resinous acids are dissolved therein, prior to their use. In practice about 10% of sodium oleate is dissolved in the oil at a temperature not exceeding 260° F.—W. L. C.

*Improvements relating to the Purification of Fatty or Oleaginous Substances, and Apparatus therefor.* W. R. Lake. From A. F. de Nuge, Paris. Eng. Pat. 15,531, November 25, 1884.

THIS patent contains the description, illustrated by drawings, of special mechanical arrangements for subjecting oils to the successive action (1) of caustic alkali, (2) of a current of steam, for purposes of purification. Three sets of vessels are described, in all of which the operations are continuous. In the first, the oil and alkali are mixed, and separated again; in the second, or "vaporising column," the oil is well steamed; in the third, the soap formed in the first operation is decomposed.—W. L. C.

*Preparation and Application of Improved Hygienic and Disinfecting Substances, for use as Candles, Nightlights, Tapers, Lamp-oil, and such like, or as External Remedies.* E. B. Watson and H. B. Fulton. Eng. Pat. 9341, August 5, 1885.

For illuminating purposes, 1 oz. of sublimed iodine is dissolved in about 50 lb. of solid paraffin (for candles) or in from 7 to 10 gallons of paraffin oil. For external remedies, in lieu of "tincture of iodine," the solution of iodine in petroleum spirit, etc., may be painted on the affected part, or solid paraffin impregnated with iodine may be used as a plaster.—W. L. C.

*An Improved Process for Preserving Crude Animal Fats.* P. A. Newton. Eng. Pat. 9380, August 6, 1885.

CRUDE fats are soaked for two days in a saturated solution of salicylic acid at 35° C., and are then packed in hermetically closed casks which are filled up with the solution.—W. L. C.

## XII.—PAINTS, VARNISHES, AND RESINS.

*Improvements in Vulcanised Keric Compounds, and in Processes for the Manufacture of the same.* H. J. Allison. From A. G. Day, of New York City. Eng. Pats. 8786 and 8787, July 21, 1885.

IN 1878, A. G. Day patented indiarubber substitute, in the manufacture of which sulphur was heated with mixtures of oils and tar, and wax was used to moderate the intensity of the action of the sulphur. According to the present patents, one-half of this sulphur is to be replaced by an equivalent quantity of a metallic sulphide—as, e.g., that of antimony. This not only performs the vulcanising function of the sulphur, but serves as "the heat controller," an office which, it is stated, it is impossible for sulphur used alone to fulfil. Small quantities of vegetable astringents are also incorporated with the mass, all operations being conducted between about 230° and 280° F.—W. L. C.

## XIV.—AGRICULTURE, MANURES, Etc.

*Hydration of Soils.* H. Helriegel. Rep. Anal. Chem. 5, 242.

THE author has investigated the rate of hydration of soils of average composition in an atmosphere saturated with aqueous vapour. The specimens were previously dried, and were exposed in the form of a column 70 mm. in height by 50 in diameter, being contained in glass cylinders of corresponding dimensions. The absorption proceeds rapidly at first, one-half of the water taken up during 700 hours' exposure being absorbed during the first 100 hours. (Comp. Chem. News, 44, 101, 209.)

The author also investigated the downward passage and distribution of water through columns of soil, with the view of throwing light upon the appropriation of the rainfall. The phenomena observed are, in respect of the same soil, similar to those of the motions of liquids in capillary tubes, and vary in intensity in proportion to the fineness of division of the soil. In regard to the retention of water, variations are observed with variations in composition of the soil. At the conclusion of the experiments the quantity held (*a*) by garden mould was 20.5 per cent.; (*b*) by a sandy loam, 23.3 per cent.; and (*c*) by sand, 19.3 per cent. (Cf. *Contrab. f. Agrikulturchem.* 14, 840).—C. F. C.

*On New Species of Potatoes.* Christy. New Commercial Plants and Drugs, No. 8.

BESIDES our potato-bearing *Solanum tuberosum*, there are, amongst the 700 species of *solanum*, about five which also bear tubers—*S. Commersonii*, *maglia*, *immitte*, *verrucosum*, *Jamcsii*,—of these *S. Commersonii* has been cultivated in its native country perhaps for some time. Experiments have been made in England to introduce some of these species and to cross them with the ordinary potato, in order to obtain a product which might

possibly not be susceptible to the potato disease. *Solanum maglia* grows in its native country, Chili, on the seashore, in loose sandy ground, and has externally much similarity with *S. tuberosum*. The plant appears to be especially suitable for England, and has been already cultivated in Chiswick in the first quarter of this century, where it produced abundantly, as many as thirty tubers on each plant, of quality equal to the ordinary potato. Recently sixty-one tubers were planted in two sections, in which those of a light colour were separated from those of a red colour. The tubers gathered were nearly all red. On the other hand, the tubers originally planted were only of the size of pigeons' eggs, but those obtained by cultivation were considerably larger. When cooked they proved of good quality. Crossing with the best sorts of ordinary potato gave some ripe berries with an abundant quantity of seeds. *S. Commersonii* (*S. Ohronidii*) occurs in Uruguay, Buenos Ayres, and Argentine, prefers stony ground, and likewise resembles the *S. tuberosum*. Cultivation experiments had little success, only a few tubers being obtained. A third sort, *S. Jamesii*, has external characteristics differing very perceptibly from the others; it grows about 10 inches high, and is distinguished by its very narrow leaves. It produced tubers abundantly, but these were considerably smaller than those originally planted. The tubers of the last two sorts were ripe earlier than those from *S. maglia*.—G. H. B.

*Improvements in Deodorising Substances for Manures.* W. H. Samson, Maidstone. Eng. Pat. 13,050, October 2, 1884.

EXCREMENTARY matter is caught in receivers containing any of the disinfectants now in common use. It is afterwards carried away in hermetically-sealed tanks and reduced by evaporation to a dry powder suitable for fertilising purposes.—C. C. H.

## XV.—SUGAR, GUMS, STARCHES, Etc.

*Apparatus for the Manufacture of Sugar.* Dingl. Polyt. J. 256, 503—506.

C. SCHERER proposes to make cloth filter-bags withstand greater pressure by placing them within a net of wire gauze. An arrangement is also shown in which the filter is surrounded by a steam jacket.

*Apparatus for Washing Carbonic Anhydride.*—The gas used in the Napajedl and Raigern sugar works is

obtained from limekilns. It enters the cast-iron cylinder A (Fig. 1) through the pipe *p*, and is constrained to pass through the water in the successive trays by means of the caps *b*. A layer of limestone on the grid *g* frees the gas from the water carried up mechanically, and also from sulphurous anhydride. The washed gas passes away through *m*; the wash-water is admitted at *f*, and flows away at *o*.

The syrup enters at *c* and leaves the tank at *d*, and passes into the test tank B, from whence it goes to the boiler. In each compartment is an agitator, *g*. Usually the gas is introduced by the perforated tubes *b* into the two chambers I. and II. only, and from these it passes to the other chambers by means of the perforations *i* in the partitions, passing away finally through *k*. Or the gas from *k* may be passed into the apparatus (Fig. 4) at

**Saturating Tank for Carbonic Anhydride.**—Forstreuter Bros. (Ger. Pat. 29,039, March 11, 1884) construct the apparatus as shown in Figs. 2, 3 and 4. The tank is divided into compartments by the partitions *ε ε* and *v v*, *m*, through which the syrup and milk-of-lime is passed from *l* to *o*, and thence into the main tank at *c*. The gas can also be passed into the main tank at *g*, if necessary, as well as, or instead of, at *b*.

*Gas-extraction Tube for Bone-black Retort.*—A. Schneider (Ger. Pat. 29,048, April 13, 1884), describes a massive cast-iron hanging retort (Figs. 5, 6, 7 and 8), down the centre of which passes a perforated gas-tube *b*, which is surrounded by small conical sleeves, *c*. Each sleeve has three ribs inside to keep it in position and to maintain a passage for the gases from the bone-black to the tube.

*Steam-worm for Vacuum-pan.*—F. Hallström (Ger. Pat. 29,538, April 30, 1884) proposes to gradually reduce the diameter of the worm from 150mm. where the steam enters to 50mm. where the steam leaves, in order to increase the efficiency of apparatus.

*Horizontal Steam Apparatus.*—F. Weigl describes an arrangement of horseshoe-shaped steam tubes which can be easily kept steam-tight. Figs. 9 and 10 show that the heating space is divided into three main compartments by means of two fixed partitions. Each compartment is divided into two smaller ones by movable partitions

ordinary way, when the process is much facilitated by the hydrogen peroxide produced. In practice forty-eight hours give good results when the layers are 3 inches thick and are frequently sprinkled and turned over. If milk-of-lime be sprinkled over the bone-black, peroxide of the alkaline earth is produced; the same thing holds good for other earths and the alkalis.—J. T.

*On the Non-crystallisable Products of the Action of Diastase upon Starch.* H. T. Brown and G. H. Morris. J. Chem. Soc. 1885, 527.

THE authors give a historical *resumé* of the above subject, and add that the present paper must be looked upon as a continuation of a previous paper by one of them (Brown and Heron, J. Chem. Soc. 1879, 596). The previous paper confirmed O'Sullivan's statement, that the properties of the products of the transformation of

screwed on to the tube-plate, one of the smaller chambers being the steam-entrance side and the other being the steam-exit side. The steam passes through two similar large valves on both sides of the apparatus simultaneously to the two outer chambers *a*, returning through the neighbouring chamber *b*; it passes from both sides into *c*, and through the middle system of tubes to *d*.

*Vacuum-pan Exhauster.*—P. Hambrich (Ger. Pat. 30,491, June 22, 1884) proposes to employ an ejection apparatus worked by a liquid which readily absorbs water, the liquid to be passed back to a reservoir tank by means of a pump.—J. T.

*The Treatment of Bone-black.* P. Degener and J. Lach. Dögl. Polyt. J. 256, 519; and Ger. Pat. 31,358, June 6, 1884.

FRESHLY-IGNITED bone-black moistened with as much water as it can take up, and exposed to light and air, produces, even in two or three minutes, a perceptible quantity of hydrogen peroxide. Bone-black thus treated is much more active than the unmoistened material. The purification of exhausted bone-black can be conducted completely, or partially and completed in the

starch by diastase can be accounted for by the presence only of maltose and a non-reducing dextrin with a rotary power of  $[\alpha]_D^{20} = 216^\circ$ .

The authors found, contrary to O'Sullivan, that the dextrins separated by alcohol from any starch transformation are susceptible to the action of diastase to the same extent as before separation. By fractionating a dextrin by repeated partial precipitation with alcohol, and then hydrolysing by malt extract or diastase the separate fractions, and ascertaining the amount of maltose produced from each, it is possible to determine whether a particular dextrin is a single substance or a mixture of dextrins. The authors found, for instance, that the dextrin in their No. 8 equation is a mixture.

The authors found it impossible to prepare a non-reducing dextrin either by fermentation or by precipitation with alcohol. Boudonneau's method (Bull. Soc. Chim. 21, 50 and 149), by boiling with cupric chloride and sufficient caustic soda to redissolve the precipitate first formed, and then filtration, acidification, and precipitation by alcohol, was not found satisfactory by the authors. They were, however, very successful with an application of Wiley's modification of Knapp's alkaline mercuric cyanide solution process (Chem. News, 46, 175), which had the great advantage, in addition to the pro-

duction of dextrins free from reducing power, of not hydrolysing the dextrin during the process.

The authors have found that a new body, to which they give the name of malto-dextrin, is produced by the limited action of malt extract upon starch. Herfeld described, in 1879, a new product, which the authors consider must have been malto-dextrin in an impure condition. The authors' malto-dextrin is non-fermentable by *saccharomyces cerevisiae* of the high fermentation; by diastase it is converted completely into maltose; alcohol only acts upon it as a whole, and does not precipitate dextrin from it. A mixture of maltose and dextrin having the same optical and reducing properties, is readily separated by alcohol into maltose and dextrin; diastase always leaves some dextrin unacted on, and the maltose readily ferments. The authors consider the composition of malto-dextrin to be  $\left\{ \begin{array}{l} C_{12}H_{22}O_{11} \\ (C_{12}H_{20}O_{10})_2 \end{array} \right.$ . Although malto-dextrin is unfermentable by the "top yeast," yet "bottom yeast"—e.g., *saccharomyces ellipticus* and *S. pastorianus*—has, under certain conditions, the power of hydrolysing and then fermenting.

A further proof of the homogeneity of malto-dextrin is supplied by dialysis, a mixture of maltose and dextrin, having the same optical and reducing properties being split up into dextrin and maltose by dialysis, whilst malto-dextrin dialyses as a whole.—F. L. T.

*Improvements in the Manufacture of Sugar and in Apparatus therefor.* A. Fesca, Berlin. Eng. Pat. 12,469, September 16, 1884.

The author states that in the manufacture of cube sugar, either in the form of prisms or plates, a uniform product is not obtained, because the liquor used in the process of liquoring in the centrifugal does not evenly penetrate the mass, owing to the obstructions offered by the partitions of the mould. This he proposes to overcome by constructing the moulds, formed of plates, as at present, with tongues or projections, so that when the whole are bolted together, an upper chamber is formed above the mould. After the sugar has been run into the moulds and centrifuged, the upper part is filled with "thick liquor" or "liquor paste," made from sugar dust. When this has set, by the withdrawal of liquor from it by absorption, the moulds are again placed in the centrifugal, and liquored in the usual way. The mass of sugar in the upper part of the moulds over the moulded portions, serves as an intermediary, and evenly distributes the liquor through the plates or prisms beneath, and this results in the formation of a more uniform product. The claims are (1) the process of "preliminary liquoring while at rest;" (2) the form of mould which enables this to be accomplished; (3) the constructions of the moulds for prisms; (4) the construction of the moulds for plates.

—C. C. H.

*Improvements in the Manufacture of Grape-Sugar or Glucose.* W. R. Lake. From W. T. Jebb, Buffalo, U.S.A. Eng. Pat. 6140, May 19, 1885.

In manufacturing glucose from Indian corn, it has been the practice to eliminate the hulls, gluten and germs from the starch by grinding the corn with water, then separating the coarse offal from the starch by sifting upon sieves, which are supplied with sprays of water, whereby the starch is washed through the meshes of the sieve, while the offal passes off over the tail; then separating the gluten and oil from the starch by treatment with caustic alkali, and repeatedly depositing and washing the starch, and then converting the refined starch so obtained. This process requires large quantities of water, and capacious receptacles for settling the starch, and is comparatively costly, while it leaves the offal in a wet, undesirable condition. It has also been attempted to manufacture glucose by grinding the corn and directly converting all the constituent parts of the grain; but this method has not been successful, as it gives impure and discoloured products. The object of this invention is to produce glucose from Indian corn, by removing the hulls, gluten and germs from the crude starch, without going to the extent of manufacturing refined starch, and consists in steeping

the corn, then detaching the hulls and germs from the starchy portions of the kernels by whipping or beating without additional water, then separating the hulls and germs from the crude starch by sifting, and then acidulating the crude starch, and converting it into glucose under pressure.—A. W.

*Improvements in the Manufacture of Hard Sugar.* W. R. Lake. From F. O. Matthiessen, U.S.A. Eng. Pat. 9326, August 4, 1885.

This is a process for transforming soft sugar into hard sugar without increasing its density, the product being a comparatively light hard sugar, having but two smooth sides, the remaining four sides having the rough appearance produced by cleavage. A layer of soft sugar, or a mixture of granulated and soft sugar, spread upon the bottom of a horizontal pan, to the depth of, say  $\frac{1}{8}$  of an inch, is subjected to pressure so as to reduce the thickness of the layer by from  $\frac{1}{10}$  to  $\frac{1}{16}$  of an inch. The extent of pressure required at this stage of the operation will vary, according to the percentage of moisture in the sugar. The more moist the sugar the less will be the pressure required. The compressed sugar is then subjected to a moderate heat for, say, six hours, whereby it is transformed into a cake of hard sugar, which is divided into cubes or blocks, by cleaving it in parallel lines both lengthwise and crosswise.—A. W.

## XVI.—BREWING, WINES, SPIRITS, Etc.

*Recent Work in Brewing.* Dingl. Polyt. J. 256, 456.

THE following abstracts are from papers which appear in the Proceedings of the third general meeting of the Berlin Union for Brewing Research and Teaching:—

*The Influence of Hops upon the Keeping Properties of Beer.* M. Haydnck.

Hops exert a two-fold influence upon the durability of beer. They check the growth of disease ferments, and also precipitate the greater part of the albuminous matter of the wort by means of the tannin which they contain. Hops also somewhat improve the yeast fermentation. The author has made experiments upon the retarding influence of hops, bacterial growth, especially the lactic acid ferment. He finds that malt mashed at 62°, and fermented at about 50°, gives a pure lactic acid fermentation, no volatile acid being formed. When, however, he ferments with addition of an aqueous extract of hops, the growth of bacteria is stopped, and a pure alcoholic fermentation takes place. The same antiseptic effect is produced by the extract from 2grms. hops per litre of wort, as by the extract from 30grms. per litre, and even  $\frac{1}{2}$ gm. per litre produces a marked effect. The author endeavoured to isolate the antiseptic substance, and concludes that the action is due to the bitter hop-resin, hop-oil and hop-tannin being without action. He finds that there is a marked difference in the antiseptic action of different kinds of hops, and that the efficacy decreased with age. Hops which had been once extracted, gave, on second and third treatments, liquids as strong in antiseptic power as the first extract. Addition of hops does not prevent acetic fermentation; in fact, the fermentation appeared to be more active in the presence of hops. Butyric acid fermentation appeared to be stopped by addition of hops; but the author is still working at the subject, and promises early results.

*Deinhardt*, continuing his researches on "hopping," finds that beer from a high-dried malt, requires a much larger quantity of hops to produce the same effect, than beer from a low-dried malt. Also, that beer hopped to a strongly bitter flavour loses a large portion of the hop-bitter on keeping. He also determines the smallest and largest quantity of hops necessary to produce a given effect, and the influence of time of boiling with hops upon the flavour of beer.

*Matz* gave the results which he had obtained with two samples of pure yeast from the Carlsberg laboratory. The beer from sample No. 1 brightened very slowly, and required to be stored for some time; but it possessed great keeping properties. No. 2 brightened very quickly, but the beer would not stand long transport.

*Francke* discussed the question whether the breaking of beer was dependent upon the condition of the barley. He ascribes a bad breaking to a deficient supply of yeast food, and concludes that it is necessary for the malt to be stored for six or eight weeks before it is used, since an undoubted molecular change goes on slowly in the stored grain. He also remarks that last year's malt was deficient in diastatic power.

*Reinicke* has experimented upon washing steeped and dry barley. He recommends that barley should be washed after steeping, to remove injurious matter, and also to remove the smell of the steeping water. He states that the difference in washed and unwashed barley can be detected by the smell of the grain on the floors during the malting process. Experiments showed that washing dry barley was ineffectual for removing the dirt particles.

*Delbrück* ascribes the reddening of white beer to a round bacterium, resembling *sarcina*. He thinks it possible to find hops which will exert an antiseptic action upon this ferment.

Vienna, and Munich—can only be obtained with the respective waters. On the other hand, Gregory maintains that the different types may be obtained with the same water.—G. H. M.

*Improvements in Apparatus for Producing Carbonic Acid Gas and for Utilising the same in Raising Malt Liquors, and for other Analogous Purposes.* C. R. Bonne, Manchester. Eng. Pat. 6821, June 4, 1885.

THE apparatus described is self-regulating in pressure and quantity of the gas produced, and hence specially suitable for raising malt liquors. An enclosed vessel *a* is supplied with water from the cistern *c* overhead. Floating upon the water in *a* is an open-topped float *d*, made of any acid-resisting material, the buoyancy of which is increased by forming the bottom hollow. The float receives a supply of acid from the acid cistern *e*, the pressure being ensured by the upper part of the cistern being connected with the generator *a*.

*Debrück* concludes that the grounds for judging a water for brewing purposes are still uncertain. An apparently bad water may yield a good sound beer; and the only sure guide is to make a brewing with the water in question.

*Noback* states that the "steep" water determines the character of the beer, that it is impossible to brew a Pilsen beer with Munich water, and *vice versa*—the inorganic constituents of the water determining the character of the beer, and that the three types of beer—Pilsen,

Suspended from the top of *a* is a perforated cage *y* containing the carbonate required. Upon starting the apparatus, water is admitted into the generator from the cistern *c*. This causes the float to rise until the flange *d'* comes into contact with a corresponding flange *a'*, thus closing the communication between the upper and lower part of *a*. Simultaneously the acid comes in contact with the carbonate, liberating carbonic dioxide, which accumulates in *a*, and forces the water back into the cistern *c*. By this means the float *d* is lowered at

the same time, and the acid not being in contact with the carbonate, the supply of gas is stopped until by reason of the gas being consumed the pressure is once more reduced; the water level is raised again, and the same operation is repeated. In order to raise a malt liquor by this machine, the latter is connected with the tank, cask, etc., by a pipe, so that the gas, after being washed in *A*, can exercise a pressure on the surface, and so cause the liquor to rise to the desired level. The degree of pressure depends upon the head of water in the cistern *c*. If it be required to work at a higher pressure, the pipe *b* is divided into two branches, one fitted with a back pressure valve to permit the water to flow from the cistern *c* only, but not to return thither, and the other branch provided with a weighted valve, which only opens when a certain pressure is reached.—S. H.

*Acidity of Beer.* A. Bertschinger. Dingl. Polyt. J. 256, 519.

ACIDITY of beer is best estimated by adding 10cc. free from carbonic acid, to a decinormal solution of soda, and, after the addition of litmus, titrating by means of decinormal sulphuric acid. Swiss beer contains from 0.12 to 0.22 per cent. free acid, reckoned as lactic acid.—J. T.

*Vent Peg adapted for Purifying the Air admitted to Fermentable Liquids.* William Henry Hall. Eng. Pat. 13,201, October 4, 1884.

THIS is an arrangement by which the air admitted through the vent to a cask or other closed vessel containing beer, etc., is made to pass through some filtering material, such as water, solution of salicylic acid or flannel, in order to remove from it impurities likely to decompose the beer.—G. H. M.

*Improvements in or relating to the Treatment of Maize in the Manufacture of Spirits.* William R. Lake. From William Thomas Jebb, New York. Eng. Pat. 4957, April 21, 1885.

THIS patent refers to the separation from maize of a starch meal free from the hulls and germs of the corns. The separation is effected by steeping the corn in warm water (about 140°) for some hours, until the kernels become swelled; the water is then drained off, and the steeped maize introduced into a machine in which it is thoroughly beaten or whipped. This reduces the starchy matter to powder, without breaking up the hulls and germs. In this way the corns are divided into three distinct products—the finely-granulated starchy portions, the germs which are considerably larger than the granules, and the still larger hulls. The three bodies are then separated by sifting, and the pure starchy bodies may be mashed and fermented. The author claims that the liberation of fusel oil, etc., is avoided by getting rid of the germs and hulls; that the conversion of the starch is effected more uniformly; that the fermentation is more under control; that the distillation of the spirit can be carried on at a lower temperature and with less loss of spirit; and that a better quality of spirits is produced. The hulls and germs may be used for fodder, or may be used for the preparation of oil-cakes. Drawings of the plant required are given, including a tank for developing the starch under pressure.—G. H. M.

*Improvements in the Manufacture of Beer.* Philip M. Justice. From Andrew W. Billings, New York. Eng. Pat. 9847, August 19, 1885.

A CERTAIN percentage of raw grain is to be added, in the manufacture of beer or ale, whereby the quantity of malt required is reduced, a superior beer produced, and a great saving in labour and expense effected. These results are obtained by making two mashes, one of malt in the ordinary manner, and the other a supplementary mash of Indian corn, rice, or other raw grain. The grain for the latter mash is ground, mixed with the requisite quantity of water at

112° F. in a special form of mashing apparatus, and the mixture then heated to about 210° F. by the injection of live steam. The paste mash so obtained is then quickly cooled to 140° by the injection of cold water, and sufficient ground malt is added to sugarify the starch. At the end of about two hours live steam is again injected, and the temperature raised to about 185°; the mash is then allowed to cool and run into the mash prepared from malt in the usual way. The subsequent operations are carried on as in an ordinary brewing. The author claims for his method complete conversion, largest yield of extract, and no extraction of oils, avoiding thereby any corn-like flavour or smell. The details of the process may be varied in several respects. A full illustrated description of the apparatus used is given.—G. H. M.

**XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.**

**(A) CHEMISTRY OF FOODS.**

*Improved Process of Preserving Smoked Fish.* O. Syllwasschy, Ellerbeck. Eng. Pat. 12,929, September 29, 1884.

THE fish are first smoked and then pickled, after which they are packed in barrels. Prior to use, and after removal from the barrels, they are washed to remove the salt, and again smoked. It is claimed that after treatment by this method the fish can be kept longer and without injuring the flavour, even of the most delicate varieties.—C. C. H.

*Improvements in the Preparation of Caseine, etc.* A. M. Clark, London. From E. E. Childs, Brooklyn. Eng. Pat. 14,240, October 28, 1884.

UNSUITED for abstracting.—C. C. H.

*Process of Treating Fish Roe, etc.* E. E. Waters, New York. Eng. Pat. 7016, June 9, 1885.

THE roes are first washed to remove the blood, salt, etc.; they are then split and macerated for twenty-four hours in an aqueous solution of ammonia containing from two to five per cent. of concentrated ammonia. After straining, the solution is either evaporated or the albumen precipitated by the addition of an acid, pressed and dried. In the latter case it is desirable to moisten the cake in a solution of ammonia before drying to gelatinise the exterior. Caustic potash or soda may be used in place of ammonia.—C. C. H.

**(B) SANITARY CHEMISTRY.**

*Report on the Waters of the Hudson River.* C. F. Chandler, Ph.D.

THIS investigation was undertaken by the author at the request of the Water Commissioners of the City of Albany. Its object was to determine whether the water of the Hudson River, the source of the supply of the city, was in any way rendered unfit for consumption by the reception of the sewage discharge of the cities situated above the intake, notably Troy, with a population of 60,000. Analysis by Wanklyn's method failed to show any considerable quantity of nitrogenous matter indicative of sewage pollution; indeed, the water supplied to Albany contained less albumenoid ammonia, after it had received the sewage of Troy, than the water from the river above Troy at a place where it is practically free from any considerable pollution. Biological examination the author considers in this case to yield a negative result, because fermentation experiments did not appear to develop any organisms which were not developed by water absolutely free from sewage pollution. With respect to the transmission of disease by a water which although polluted has by oxidation undergone purification, after reviewing the opinions of Huxley, Tidy, Letheby, Angus

Smith, Magnen, and others, he concludes that it does not appear to rest on any substantial basis that diseases have ever been transmitted by a water which would not have been condemned by the ordinary methods of analysis. Koch's theory he views in a similar light, and does not consider it fairly established. In conclusion, notwithstanding the pollution of the Hudson by the sewage discharge of the city of Troy, Professor Chandler maintains that dilution combined with oxidation effectually removes all evils which might accrue from the pollution. After comparison with the water supply of European cities, and a comparison of the death-rate of the leading American cities, he sees no reason why the source of supply should not be considered a good one, and views the objections raised as more sentimental than sound.—C. C. H.

*Tarred Water Pipes.* W. Thörner. Chem. Zeit. 1885, 926.

TARRED water pipes frequently contaminate the water if the tarring is not properly done. It is best, where practicable, to dip the pipes, when sufficiently cool after casting, in a liquid which wets them easily (alcohol, petroleum, crude benzene, toluene, etc.). The liquid thus used must mix readily with tar and easily evaporate. After moistening, the pipe is tarred by immersion.—J. T.

*Improvements in the Preparation of Agents to be used in the Treatment of Sewage, etc., and in the Treatment of such Matters.* J. W. Slater, London. Eng. Pat. 12,830, September 26, 1884.

(1.) PEAT is mixed with water and ground to a thin mixture. (2.) Iron slags or slag wool are treated with hydrochloric acid, sufficient to convert the whole of the alumina into chloride, and leave a slight excess of acid. The sewage is treated by adding from twenty to thirty parts of mixture (1) to 10,000 parts of sewage, and subsequently with six to eight parts of mixture (2). The organic matters in solution and suspension are precipitated and allowed to subside. The quantity of clay used in (1) depends on the temperature of the sewage—ordinarily from twenty-five to thirty per cent. of the weight of the solid matter in the peat, and the lower the temperature the less the quantity required. The slag should be free from oxides of iron, lime, magnesia, and alkalis. Chloride of copper may be used to oxidise the iron salts present. If more than thirty grains of organic matter per gallon of sewage is present, larger proportions than above specified are used. The claims are: (1.) The treatment of sewage by the mixture of peat and clay; (2.) The treatment by the subsequent addition of the solution of the slags in hydrochloric acid.—C. C. H.

*Improvements in Filters: a Device for Cleansing the Filtering Bodies of the same.* C. E. Chamberland, Paris. Eng. Pat. 6646, June 2, 1885.

THE author in a previous patent described the construction of a filter which removes the suspended matter from water and also the microbes and germs. This consists of a cylinder of fine porcelain through which the water is forced from the exterior to the interior. In operating upon a large quantity several of these are placed in a closed vessel; for removing the deposited matters from the surface of the cylinders the device described in this specification is intended. Two plates which have holes encircling the filtering cylinders are bolted together and nip between them canvas, rubber, or asbestos, so as to fit tightly against the exterior of the porcelain cylinders. A central screw forces the plates from end to end of the containing vessel, and thus scrubs off the solid matter from the cylinders. Steam may also be used for regenerating the porcelain.—C. C. H.

*Improved Process for the Economical Production of a Porous Carbon, etc.* G. E. Ellis, Newton Abbot. Eng. Pat. 7318, June 16, 1885.

THE material used is the carbonaceous clay deposit found above the Devonshire lignite beds; the open face

deposits are preferred. After a preliminary drying the clay is pulverised and incorporated with ten to fifteen per cent. of lignite, fifteen to twenty-five per cent. of aluminous schist, one to two per cent. of coal-tar or pitch, and is then formed into blocks in a brick press. After drying, the bricks are heated in retorts and finally granulated.—C. C. H.

## XVIII.—ELECTRO-CHEMISTRY.

*Improvements in Secondary Batteries.* Alexander Henry Reed, Middlesex. Eng. Pat. 14,508, November 3, 1884.

By this invention a secondary battery is constructed, instead of with lead, with zinc in an alkaline solution, and not, as is usual, in an acid solution. Consequently the oxide of zinc on dissolution in the potash or soda, or any other metallic oxide soluble in alkalis, is employed in the construction of the pile, the positive pole of which is constituted by hydrates of oxides or anhydrous oxides insoluble in potash or soda as depolarisers.—T.

*Improvements in the Manufacture of Carbons for Incandescent Electric Lamps.* Mortimer Evans and Frank Wynne, Lambeth, London. Eng. Pat. 12,675, September 22, 1884.

THIS invention has regard to material from which carbon filaments may be produced, and to the treatment of this, and consists in first obtaining a substance of a homogeneous nature, composed of a substance which may be carbonised, and treating it in such a way as to form filaments or threads of uniform sectional area and quality.—T.

*Improvements in the Construction and Application of Carbon or Carbonaceous Electrodes for Primary and Secondary Elements.* Richard Heber Radford, Sheffield, Yorkshire. From Hermann Friedrich Bonté Schaefer, Berlin.

IN order to form electrodes of carbon, or carbonaceous material in large sizes, a hose (i.e., a flexible tubular case or envelope) is filled, during its production by the machine, with small particles of carbon or carbonaceous material, and pressed in firmly, and in such a manner that the production of the hose progresses in the same ratio as it is filled.—T.

## XIX.—PAPER, PASTEBOARD, Etc.

*An Improved Cold Process for the Manufacture of Paper Pulp and Bleached or Unbleached Textile Fibres, and Apparatus therefor.* Hippolyte Vessier and Amédée Willaoux. Eng. Pat. 14,859, Nov. 11, 1881.

THE process consists in treating the material, such as straw, esparto, flax, cotton, old papers, wool, rags, etc., with a cold solution of caustic soda, varying in strength from 10° to 25° B. After steeping in this bath for one to eight hours, according to the nature of the material, it is washed in a special apparatus, a drawing of which is given, and bleached with a solution of bleaching powder and salt, in the proportion of one part of the former to seven parts of the latter.—E. J. B.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

*Work of the Pharmaceutical Commission.* Arch. Pharm. (1885), 23, 466, 497.

THE work of the commission begins with the publication of elaborated articles on the Pharmacopœia, and from it statements of general interest are selected.

*Vinegar.*—Concerning the colour an alteration is made therein, that the vinegar must be colourless or feebly yellow, whilst the Pharmacopœia allows a yellow colour. The residue on evaporation must not exceed 0.5% against the former exceedingly high 1.5%.

**Borax.**—The former statement of the special reaction, "The aqueous solution turns turmeric paper brown on the addition of hydrochloric acid," is amended by the following: "The aqueous solution reacts alkaline; it turns turmeric paper brownish-red after some time, even after acidification by hydrochloric acid."

**Bromine.**—The statement concerning the solubility in water is affirmed in that it dissolves in 30 parts of water at 15°. The estimation of the solubility in sodium hydrate is extended in that this solution must separate no oily droplets, nor give out a smell like chloroform, which would indicate the presence of bromoform. A rough test for the amount of chlorine is given, which allows about 3, to pass. 1cc. of the bromine solution (1 in 30) is diluted with 9cc. water, and a small excess of ammonium carbonate and silver nitrate is added and well-shaken up. After filtration the filtrate, on the addition of nitric acid, must not show more than an opalescence.

**Extracts.**—In testing for copper, the acidified solution is to be heated to boiling, and then cooled before testing with an iron rod.

**Solubility.**—Traces of alumina are allowed. Diluted with 15 parts of water and acidified with acetic acid, the addition of barium nitrate or of silver nitrate and nitric acid must not produce more than opalescence. This test excludes 0.15% chlorine and 0.3% sulphuric acid.

**Opium.**—The following directions are given for testing this much-discussed subject of research, and the minimum quantity of morphia is put at 10%; 8grms. powdered opium are placed on a filter of 80mm. diameter, and are gradually washed with 18grms. of ether, the funnel being kept covered. The opium is then dried in a water bath and shaken in a flask with 80grms. water at 15°. After standing half-a-day, 42.5grms. of this aqueous opium extract are filtered off into a flask, 12grms. alcohol, 10grms. ether and 1grm. ammonia being added, and the mixture is kept in a closed vessel with frequent shaking for 12 hours at a temperature of 10 to 15°. A weighed filter of 80mm. diameter is then moistened with ether, and the ethereal layer from the flask is poured on it, and afterwards the whole contents of the flask, after shaking with 10grms. more of ether, are placed on the filter. The morphia crystals are then washed with a mixture of 2grms. dilute alcohol and 2grms. ether, and are weighed after a final drying at 100°. The weight must not be less than 0.4grm.

**Tinctures.**—The preparation is to consist of maceration for eight days in a well-closed flask in a shady place. Recourse to digestion is abandoned, because the much simpler maceration gives much more durable and quite as strong a tincture.

**Wood Vinegar.**—Testing for hydrochloric acid is added.

**Chloride of Lime.**—This must contain at least 20% of available chlorine.

**Water-Glass.**—The testing is extended to the estimation of caustic or carbonated alkali, because the presence of these renders it unsuitable for bandages. The following test is given: If equal parts of water-glass and spirits of wine are triturated together in a basin, a granular salt (tri- or tetrasilicate) must separate, and not a pappy (monosilicate) or greasy salt (bisilicate), and the filtered solution must not turn turmeric paper brown.

**Liquid Paraffin.**—A paraffin of at least 880 sp. gr. is required, whilst the present pharmacopœia only specifies 840 sp. gr. It must not boil below 360°. As a test of purity for the liquid, as well as for the solid paraffin, the following is given: 3grms. paraffin heated with 3cc. H<sub>2</sub>SO<sub>4</sub> in the water bath, with frequent stirring for 15 minutes, must not produce a change in the paraffin, and the sulphuric acid must only be slightly coloured brown.

—G. H. B.

#### Cod-liver Oil and Iron. Pharm. Zeit. 30, 507.

For the preparation of this drug, ferric benzoate is the most suitable. 60grms. toluenebenzoic acid dissolved in 300cc. boiling water are treated with 102grms. ammonia solution (10%). To this solution is added a mixture of 100grms. ferric chloride solution (10% Fe.) and 300cc.

water, and the precipitate is washed on a filter until free from chlorine; it is then pressed and dried. 20grms. of this ferric benzoate, together with 5grms. toluenebenzoic acid, are rubbed together with some cod-liver oil and then digested with 1 kilo. cod-liver oil on the water-bath, with stirring for one hour. The cod-liver oil and iron thus prepared is filtered whilst warm; it contains 2% ferric benzoate, or 0.3% Fe., has a good taste, and owing to the free benzoic acid it keeps well.—G. H. B.

#### Compounds of the Alkaloids with Iodine Chloride. M. Pittuar. Ber. 18, 1612.

A GENERAL reaction for pyridine and quinoline, and their alkaloid and other derivatives, consists in their combination with chloride of iodine to form very characteristic addition products containing one CH for each pyridine-ring.

Thus, if X be an alkaloid containing one pyridine-nucleus, it will form a compound of the formula XI<sub>2</sub>Cl, and if Y contain two pyridine-rings it will form a compound YI<sub>2</sub>Cl<sub>2</sub>.

These bodies are, for the most part, sparingly soluble yellow precipitates, which are produced by adding to a solution of the alkaloid a solution of iodine chloride in HCl, or a mixture of KI, KNO<sub>3</sub> and HCl (the latter solution is not always suitable). With an excess of chlorine they can form unstable compounds of the formula XI<sub>2</sub>Cl<sub>2</sub> corresponding to iodine trichloride. They are readily attacked by NaOH and by NH<sub>3</sub>, and with the latter they form compounds of the constitution XNII<sub>2</sub>; these are dull-green or dull-red unstable bodies, insoluble in water, converted back into the chlorides by HCl, and decomposed on boiling with alcohol according to the equation—

thus evolving one-third of their nitrogen.

These iodoammonia compounds are also produced by the combination of the alkaloid with iodide of nitrogen (NII<sub>2</sub>). The author is inclined to consider that the latter bodies are molecular compounds of the base with iodide of nitrogen, and that the chlorides are molecular compounds of the base with ICl.

The hydroxyquinolines in which the OH group occurs in the benzene-ring, and tetrahydroquinoline and its derivatives do not combine directly with chloride of iodine, and are thus exceptions to the general rule.

The following are the reactions of some of the alkaloids and derivatives of quinoline towards this reagent:—

**Theobromine and Caffeine.**—No effect, since they are not derivatives of pyridine or quinoline.

**Morphine.**—Separates iodine.

**Quinodine.**—Light-brown amorphous ppt.

**Quinine.**—Light-brown crystalline ppt.—

**Quinidine.**—Light-yellow ppt. scarcely soluble in HCl.

**Cinchonine.**—Light-yellow ppt.

**Brucine.**—Light flocculent ppt.

**Strychnine.**—Yellow ppt., soluble in HCl.

**Papaverine.**—Yellow flocculent ppt., slightly soluble in HCl.

**Codaine.**—Ppt. soluble in HCl.

**Thebaine.**—Whitish ppt.

**Narcene.**—Greenish-yellow ppt., soluble on heating, and reprecipitated as light-yellow needles.

**Piperine, piperidine, acetonine, veratrine, narcotine, thebaine, codaine, and conevine.**—Yellow ppts.

**Cocaine.**—Light-brown crystalline ppt.

**Nicotine and Atropine.**—Yellow ppts. which dissolve on heating and reprecipitate as compact brown crystals.

**Pyrol.**—Black insoluble body (C<sub>12</sub>H<sub>10</sub>N<sub>2</sub>Cl<sub>2</sub>).

**p-Toluyloquinoline.**—Easily soluble reddish-yellow needles, C<sub>10</sub>H<sub>7</sub>N<sub>2</sub>Cl<sub>2</sub>HCl; melting point 112°, blackened by NH<sub>3</sub>.

**β-Naphthoquinoline.**—Light-yellow needles—

melting point 148°, soluble in HCl, blackened by NH<sub>3</sub>.

*Antipyrine*.—Light-yellow needles,  $C_{11}H_{10}N_2O$ ,  $10N_2Cl$ ; melting point  $142^\circ$ , soluble in alcohol, blackened by  $NH_3$ .

*Hydroxymethylquinoline*.—Yellow needles, soluble in alcohol, blackened by  $NH_3$ .

*Quinidine*.—Yellow needles, melting point  $151^\circ$ .

*Quinoline*.—Light yellow ppt.—

insoluble in alcohol.—A. G. G.

*Reaction between Brucine and Strychnine*. A. Hanssen, Ber. 18, 1917.

THE author has submitted brucine and strychnine to a similar process of oxidation with chromic and sulphuric acids. The resulting product is the same in both cases, and has the formula  $C_{16}H_{13}N_2O_4$ . It appears, therefore, that in the case of strychnine, the group  $C_2H_5$ , in that of brucine the group  $C_2H_5O$ , have been eliminated. The author explains this by supposing that the group  $C_2H_5$  represents a benzene ring, joined to the group  $C_{14}H_{11}N_2O_3$ , as in "diphenyl." The explanation is borne out by the fact that strychnine forms nitro- and bromo-substitution products, which is not the case with the oxidation product. In the same manner the group  $C_2H_5O$ , split off by oxidation from brucine, is supposed to be a dimethoxy-benzene group, and brucine a dimethoxy-strychnine.—J. B. C.

*Action of Caustic Alkalies on Cinchonine and other Cinchona Alkaloids*. A. Krakau, Ber. 18, 1934.

THE action of caustic alkalis was effected at a temperature of about  $200^\circ$ , in a current of superheated steam. By modifying the usual method in this way, the author obtained quinoline, lepidine, a solid substance remaining in the residue, and a thick oil which distilled with the other bases. The separation of the quinoline bases from this product was effected by steam. From cinchonidine, quinine and quinidine, similar products were obtained by the same method.—J. B. C.

*Ascepol (Orthophenylsulphonic Acid)*. E. Serrant, Compt. Rend. 100, 1465.

THIS compound is said to possess greater antiseptic properties than phenol, and its action is less injurious than that of phenol.—D. B.

*Kolbe's Synthesis of Salicylic Acid*. R. Schmitt, J. Prakt. Chem. 31, 397.

FROM the transformation of potassium phenylsulphate into potassium paraphenylsulphate, Baumann (Ber. 11, 1910) supposed that in the preparation of salicylic acid sodium phenylcarboxylate was at first formed, and was subsequently converted into sodium salicylate. This hypothesis is confirmed by Hentschel (Ber. 16, 795), who showed that in the presence of another molecule of sodium phenol, sodium phenyl-carboxylate is decomposed with the formation of disodium salicylate. In the present paper it is shown that by the absorption of carbon dioxide sodium phenol is readily converted into sodium phenyl-carboxylate, which, on heating, is completely transformed into the isomeric sodium salicylate. When sodium phenyl-carboxylate is heated with one molecule of sodium phenol, disodium salicylate and free phenol are obtained.—D. B.

*Study of the Alkaloids*. O. de Coninck, Bull. Soc. Chim. 43, 236–247.

(3.) *Quinoline bases*, as observed by Williams, are polymerised by sodium; their chloroplatinate, as mentioned (Ber. 16, 2682), are not decomposed by boiling with water. Carbon disulphide acts very slightly on quinoline, a very small quantity of transparent crystals being produced after two or three days.

(4.) *Cotinine*.—Carbon disulphide readily acts on this base, producing, without evolution of sulphuretted

hydrogen, a thick, yellow-brown, unpleasantly-smelling fluid. The chloroplatinate of pure cotinine is incompletely decomposed by boiling water, whilst the double platinum salt of commercial cotinine (containing methyl-cotinine) undergoes complete decomposition; the two phases of Anderson's reaction, however, do not occur. On dissolving the platinum salt of the impure base a red oil separates, which is only taken up by water on warming, and solidifies in the cold to a resinous mass.

(5.) *Nicotine*.—Carbon disulphide has no action, and the chloroplatinate is not decomposed by boiling water. The base, as shown by Etard, is oxidised by mercuric oxide, whilst  $\beta$ -lutidine (from brucine) and  $\alpha$ -collidine (from cinchonine) are not attacked by this reagent.

The author compares the properties and behaviour towards chemical reagents of the pyridine bases, the alkaloids, and the quinoline bases, and adds some observations on the resinous masses obtained by the distillation of the ammonium iodides of the pyridine bases with potassium hydroxide. He further remarks that, in addition to the suffocating odour occurring in this process (Hofmann, Ber. 14, 1497), a red colouring matter is produced, readily recognisable on treating the product of the reaction with acidified water. The colour and the odour together serve as a test for small quantities of pyridine bases. At the conclusion of the foregoing work, the author mentions the action of sodium on piperidine, cotinine, and nicotine. Piperidine does not appear to be polymerised by this metal, either in the cold or at high temperatures. Commercial cotinine is converted into a yellow crystalline substance readily soluble in, but not decomposed by, water. Pure cotinine is likewise converted by sodium into a crystalline compound, from which cotinine is regenerated by the action of water. This difference in behaviour might serve to distinguish pure from impure cotinine. Nicotine submitted to the action of sodium produces, after many weeks, a solid substance, which, by contact with water, reproduces an oil having the character of nicotine.—F. L. T.

*Sodium Orthovanadates and Analogous Salts*. Harry Baker, J. Chem. Soc. 1885, 353.

RAMMELSBERG (Ber. 15, 1674) and Mendeleeff previously questioned whether the phosphates should be considered as allied to the vanadates. After Ditte (Ber. 18, Ref. 4) had shown that vanadium could replace phosphorus in the Apatite and Wagerite groups, the author sought to establish the same point by the study of the orthovanadates. (1.) *Sodium orthovanadate*,  $Na_2VO_4 \cdot 12H_2O$ .—Hitherto the only known salt was that with  $16H_2O$ , described by Roscoe. By fusing vanadic acid with sodium carbonate, and treating the aqueous extract of the melt with caustic soda, the vanadate crystallises in longer or shorter hexagonal prisms with basic terminations (the rhombohedron being occasionally indicated) quite analogous to the orthophosphate and arsenate. A crystal of the vanadate continues to grow in a solution of the phosphate, and a small crystal of any of the three salts causes crystallisation of supersaturated solutions of the others. In the preparation of the salt described, three other salts were obtained from the alkaline mother-liquor. (2.) *Sodium orthovanadate*,  $Na_2VO_4 \cdot 10H_2O$ , in two modifications, the one crystallising in well-defined, clear rhombic dodecahedra, the other in thin hexagonal plates,  $\alpha$  P.O.F. (3.)  $Na_2VO_3 \cdot H_2O$  (?) occurs in rhombic plates. The salt can only be isolated by the mother-liquor being carefully decanted and the crystals repeatedly washed with alcohol diluted so that no precipitation occurs. The phosphates and arsenates corresponding to the last three vanadates have already been observed by the author, but not as yet prepared in any quantity. (4.) *Sodium fluovanadate*,  $2Na_3VO_4 \cdot NaF \cdot 19H_2O$ , is obtained either by fusing together of the corresponding amounts of vanadic acid, sodium carbonate, and sodium fluoride, and crystallising from a warm aqueous solution, or by adding the calculated quantity of sodium fluoride to a saturated solution of sodium orthovanadate, or pyrovanadate with excess of caustic soda. The salt forms clear regular octohedra, which can be recrystallised from dilute caustic soda solution. The corresponding sodium fluophosphate has been

frequently described, lastly by Rammelsberg (*Ber.*, 14, 589). Sodium fluoroarsenate,  $2\text{Na}_2\text{AsO}_4 \cdot \text{NaF}$ , 1911.0, forms shining isotropic octohedra. The author also examined the indices of refraction of the salts described.—F. L. T.

## XXI.—EXPLOSIVES, MATCHES, Etc.

*Magnesium for Bengal Lights.* Dingl. Polyt. J. 256, 518.

THE chemical firm late E. Schering, in a circular, recommends the following mixtures:—For white fire, 1 part shellac, fused with 6 parts barium nitrate, ground and mixed with 2.5 per cent. of magnesium powder. For red fire, 1 part shellac, 5 parts strontium nitrate, fused together, ground, and mixed with 2.5 per cent. of magnesium powder. These mixtures can be made into ribbons about a finger's breadth, or they may be charged into thin zinc tubes so as to make magnesium torches. On burning, the zinc case burns with its contents.—J. T.

## XXII.—GENERAL ANALYTICAL CHEMISTRY.

*Apparatus for Volumetric Analysis.* Dingl. Polyt. J. 256, 502–503.

J. Greiner describes the burette shown in Fig. 1. A brass rod *d*, carried by a suitable stand, has its bottom end into a stopper *f*, whilst at its upper end is an arm *e*, encircling the burette and forming a screw surface. Affixed to the tube is a ring *a*, bearing a tooth *b*, Fig. 2. In using the burette the ring *a* is so fixed that the tube rests air-tight on the stopper *f*. On turning the tube the

tooth *b* slides up the screw path *e*, by which the tube is raised from *f*, and its contents can escape.

K. Bourdon describes a burette arrangement which requires no stand. One neck of a three-necked bottle contains a dipping tube V, Fig. 3; the second neck contains

a T-tube T, which connects V, the burette B, and the jet D. On compressing the indiarubber ball F, placed in the third neck, closing the clamp D, and opening the clamp C, the burette B is filled with acid. The scale S is so placed that its zero point coincides with the top of the liquid column.—J. T.

*New Laboratory Apparatus for the Continuous Production of Gas.* M. Gaston Tissandier. Bull. de la Soc. Chim. de Paris, March 5, 1885.

THE forms of apparatus usually employed for the preparation of hydrogen, carbonic acid and sulphuretted hydrogen, have this serious disadvantage—viz., that the rate of production of the gas gradually diminishes as the acid employed becomes saturated with the particular salt

formed. The object the author had in view in devising the present form of apparatus was to overcome this difficulty, and to enable him to command the production of a steady stream of gas. The apparatus consists of a glass vessel, furnished with three tubulures. It is filled with the material to be acted upon from the top M, which is then covered with some impervious material. The acid, suitably diluted with water, is contained in a reservoir, and flows through the cock R, by way of the side tube A, thus entering the apparatus from below. After acting upon the material contained in the lower part of the apparatus, the acid passes away by the U-tube T. The gas generated escapes through the tube D, attached to the upper tubulure. As the material in contact with the acid becomes dissolved, its place is supplied from above. In this way a constant supply, both of fresh acid and fresh material, is maintained, and the rate of production of gas is kept perfectly constant. The rate can be regulated by controlling the flow of fresh acid by means of the cock R.—E. J. B.

*Estimation of the Halogens.* G. Weiss. Rep. Anal. Chem. 5, 238.

THE halogens must be in the state of hydriacids; salts of ammonium should be avoided, and the solutions should be neutral. The tubes *c* and *d* are filled with solution of iodide of potassium; the solution or substance is placed in *b*; a gentle stream of air is passed through from *a* to *c*. A slight excess of strong solution of neutral ferric sulphate is run into *b*, and the mixture slowly raised to the boiling point. The reaction which takes place is as follows:—

The iodine carried over by the steam and air is dissolved in the iodide of potassium, and determined by the usual

method. No bromine is carried over if the solution be neutral. The residue in *b* is cooled, a slight excess of permanganate of potassium added, and the vessel again warmed in a water-bath to 50 to 60 C. The bromine vapour which is then evolved is drawn into and absorbed

by dilute ammonia placed in *c* and *d*, and then either volumetrically or gravimetrically determined as silver bromide. In the final residue in *b* the chlorine may either be directly determined or calculated from a determination of the total halogens.—T. L. B.

*Iron Analysis.* O. Gmelin. Chem. Zeit. 1885, 925.

*Sulphur Estimation.*—The sulphur is determined, after evolving it as sulphuretted hydrogen, and passing this through two U-tubes furnished with bulbs, which contain permanganate solution. Some concentrated solution of sodium carbonate is introduced into the decomposing flask before the hydrochloric acid is added, so that the carbonic acid evolved may expel air.

*Phosphorus Estimation.*—The sulphuric acid solution freed from silica, is evaporated in a platinum dish, and the residue is gently ignited. After dissolving in hydrochloric acid, the phosphorus in the form of phosphoric acid is precipitated with ammonium molybdate solution, a final precipitation with magnesia mixture being made.

—J. T.

*The Volumetric Determination of Manganese in Alloys, Minerals, etc., by means of Potassium Chlorate.* W. Hampe. Chem. Zeit. 9, 1083.

The method has been already described by the author two years ago, and the present paper describes the results of subsequent work, considerable space being given to discussion of the observations of other experimenters. A historical notice includes the names of Rammelsberg, Wächter, Hannay, E. Thomson, Ford, Kent, Troilius, Williams and Raymond. The process consists of the precipitation of manganese as hydrated peroxide from its solution in strong nitric acid, by the addition of potassium chlorate at a boiling temperature, and the titration of the peroxide by iron salt and permanganate. The solution must not contain sulphuric or hydrochloric acids, and where these occur their removal is effected by means of barium nitrate, or by boiling with nitric acid respectively. It is essential that the solution of the metals be in nitric acid, of sp. gr. 1.4, and if the acid be weaker than this it must be boiled down until heavy white fumes are evolved, when the necessary concentration is reached. A large excess of acid is without hindrance to the reaction. In the presence of acid of less sp. gr. than 1.4, a portion of the manganese escapes precipitation by forming permanganic acid. To describe the process shortly, the solution in strong nitric acid is heated to boiling in a flask, and potassium chlorate is dropped in, a crystal at a time, as long as green vapours are evolved; when the manganese has become completely precipitated, further addition of the chlorate produces only scarcely-perceptible coloured vapours. Five minutes' boiling is necessary to complete the precipitation. Cold water is then added to the still warm solution, and this is then quickly filtered through a paper filter, and the precipitate is washed.

The precipitate is then washed off the filter into a flask, acidified iron salt solution is added, which dissolves the precipitate, and the excess of iron salt is determined by titration with permanganate. The manganese peroxide obtained by this method has constantly the composition  $MnO_2$ , on which the standard solutions used are based. The observations of Ledebur, Kent, Mackintosh, Volhard, Pattinson and Wollf, on the reaction, are noticed. In the presence of cobalt and bismuth, the precipitate should be dissolved in nitric acid, and a little oxalic acid, and reprecipitated as before, in order to obtain exact results. Potassium bromate does not work so well as the chlorate. Where the percentage of manganese is small, as much as 20grms. or more of substance may be used without inconvenience. A series of results obtained in presence of other metals is given to show the exactitude attainable. The treatment most convenient in special cases, as for certain alloys and minerals, is described at length. The author considers this method to equal in exactness and universal application the phosphoric molybdic reaction.—G. H. B.

## New Books.

**HANDBOOK OF TECHNICAL GAS ANALYSIS, CONTAINING CONCISE INSTRUCTIONS FOR CARRYING OUT GAS-ANALYTICAL METHODS OF PROVED UTILITY.** By CLEMENS WINKLER, Ph.D., Professor of Chemistry at the Freiberg Mining Academy. Translated with a few additions by GEORGE LUNGE, Ph.D., Professor of Technical Chemistry at the Federal Polytechnic School, Zurich. London: John Van Voorst, 1, Paternoster Row, 1885.

LARGE 8vo volume, bound in cloth, containing Translator's and Author's Prefaces, Table of Contents, Introduction, subject matter covering 122 pages, and an Alphabetical Index. The work is illustrated with 55 well-executed woodcuts. The subject matter is subdivided as follows:—Chapter I. On taking Samples of Gases. II. On the Measurement of Gases. III. Apparatus and Methods for carrying out the Analysis of Gases. (i.) Estimation of Gases by Absorption. (ii.) Estimation of Gases by Combustion. (iii.) Gas Analysis and Gas-volumetrical Analysis by means of Lunge's Nitrometer. An Appendix which completes the work, contains a series of useful Tables for Reference and Employment in the Calculations involved in the Analytical Operations.

**THE ART OF SOAP-MAKING. A PRACTICAL HANDBOOK OF THE MANUFACTURE OF HARD AND SOFT SOAPS, TOILET SOAPS, ETC.** Including many NEW PROCESSES, and a Chapter on the RECOVERY OF GLYCERINE FROM WASTE LEYS. By ALEXANDER WATT. [Second Edition, carefully revised.] London: Crosby, Lockwood & Co., 7, Stationers' Hall Court, Ludgate Hill, 1885.

OCTAVO volume, bound in cloth, containing Preface, Table of Contents, and 228 pages of subject matter, followed by an Alphabetical Index. The work is illustrated by 36 woodcuts, and the Chapters are divided as follows:—Chap. I. Saponification Explained. II. The Soap Factory—its Apparatus and Appliances. III. Materials used in Soap-making. IV. Caustic Leys. V, VI, and VII. Manufacture of Hard Soaps. VIII. Making Soap by the Cold Process. IX. Oleic Acid—Soap from Recovered Grease. X. and XI. Cheapened Soaps. XII. Disinfecting Soap. XIII. Saponification under Pressure. XIV. Various Processes. XV. and XVI. Manufacture of Soft Soaps. XVII. Manufacture of Toilet or Fancy

Soaps. XVIII. and XIX. Manufacture of Toilet Soaps. XX. Soft Toilet Soaps. XXI. Medicated Soaps. XXII. Miscellaneous Soaps. XXIII. Miscellaneous Processes. XXIV. Alkalimetry—Methods of Determining the Percentage of real Alkali in Potash, in Commercial Soda-ash, Potash, and Caustic Alkali. XXV. Methods of Analysing or Assaying Soaps. XXVI. Purifying and Bleaching Oils and Fats. XXVII. Recovery of the Glycerine from Waste or Spent Leys. XXVIII. Useful Notes and Tables.

A TEXT-BOOK OF TANNING: A TREATISE ON THE CONVERSION OF SKINS INTO LEATHER, BOTH PRACTICAL AND THEORETICAL. BY HENRY R. PROCTER, F.C.S., of Lowlights Tannery, Examiner in Tanning to the City and Guilds of London Institute. London: E. & F. N. Spon, 125, Strand. New York: 35, Murray Street. 1885.

THIS 8vo volume, well bound in cloth, contains 274 pages of subject matter and an alphabetical index. It is illustrated by eight photographic plates, and with 67 well-executed wood-cuts.

Though the name of Mr. Procter, as the author of the work, is a guarantee for the practical value of the information given, yet a summarised list of the subdivision of the text into chapters will indicate the mode of treatment followed, and the compass of that treatment.

Chapter I. Anatomical Structure of Hide. II. Chemical Composition of Hide. III. Commercial Tanning Materials. IV. The Chemistry of Tannins. V. Water as used in Tanning. VI. Methods of Chemical Analysis for the Tannery. VII. to XI. Sole-leather—Preparing the Hides—Unhairing Hides—Tanning Materials—Treatment in the Tan-house—Treatment in the Shed. XII. Dressing Leather. XIII. Curring. XIV. Enamelled, Patent, or Japanned Leather. XV. Morocco Leather. XVI. Russia Leather. XVII. Chamois, or Wash-leather. XVIII. Crown Leather, or Preller's Leather. XIX. Mineral-tanned Leather. XX. Calf-kid. XXI. Glove-kid. XXII. Construction and Maintenance of Tanneries. XXIV. Commerce, Statistics, and Bibliography.

Chapter XXIV. is very carefully compiled by Mr. C. G. Warnford Lock, as well as Chapter III. From the list of works of reference we miss, however, the name of the *Journal of the Society of Chemical Industry*, with its special Chapter XIII. devoted to Tanning, Leather, etc., and the valuable paper of Mr. W. J. A. Donald, on the Chromate Process of Tanning, *J. Soc. Chem. Ind.* vol. iii. p. 615.

## Monthly Patent List.

### ENGLISH APPLICATIONS.

1885.

#### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

12484 A. Brin, London. An improved refractory substance or material suitable for lining furnaces, or for other purposes where a material capable of withstanding a high temperature is required. October 19.  
12592 J. C. Mewburn, London.—Communicated by C. C. Peck, France. Improvements in distilling and concentrating liquids, and apparatus therefor. October 27.  
12597 A. Stewart and C. Stewart, Glasgow. Improvements in the fittings and application of injectors for burning liquid fuel in furnaces for generating steam, smelting and melting metals, consuming smoke, and similar purposes. October 29.  
13089 T. B. Lightfoot, London. Improvements in machinery or apparatus for refrigerating or producing ice. October 30.

13250 W. Jarvis, Banbury. Pumps for liquids or fluids. November 3.  
13272 J. W. Holden, London. Improvements in apparatus for economising fuel and consuming smoke in, and otherwise increasing the steam generating properties of boilers, partly applicable to ventilating purposes. November 3.  
13466 E. Solvay, Liverpool. New or improved apparatus for, and process for producing, applying, and keeping up extreme temperatures. Complete specification. November 6.  
13583 R. H. Ittersum and J. Williamson, Glasgow. Improvements in tubular heating and cooling or condensing apparatus. November 9.  
13779 F. B. Welch, Manchester. Apparatus for grinding or reducing solid materials, and for mixing fluids or semi-fluids thereof. November 12.  
13799 L. H. Pearce, London. Improvements in distilling liquids and in apparatus therefor. November 12.  
13839 J. G. Robinson, Halifax. An improved construction of regenerative or recuperative furnace, applicable to gas, iron, steel, glass or other furnace. November 13.

#### II.—FUEL, GAS, AND LIGHT.

12540 H. M. Morrison, London.—Communicated by J. G. Hathaway, United States. Improvements in apparatus for pulverising fuel and feeding it to furnaces or fires for combustion therein. October 20.  
12599 E. V. Gordon Hadow, Buxted. An improvement in the artificial manufacture of coal, so as to render it comparatively smokeless. October 21.  
12902 H. Harrison, London. Improved apparatus for regulating the supply of gas. October 21.  
12938 H. Harris, London. Purification of gas in its passage direct from the meter previously to its entering into the service pipes, thereby improving the illuminating power and economising the consumption and smoke therefrom. October 22.  
13511 F. J. Jones, London. Improvements in gas producers, and a method for securing the complete combustion of gases in boiler and other furnaces. October 22.  
12686 S. F. Smith, London. Carrying off the products of combustion from gas and other lights. October 23.  
12721 J. Lucas Balfour and J. Lane, London. Improvements in the manufacture of illuminating gas and volatile liquid hydrocarbons. October 23.  
13003 J. Murray, Glasgow. An improved method of creating a current of air in combustion apparatus, and applying the products of combustion to vapour generators. October 29.  
13040 R. Mitchell and R. B. Main, Glasgow. Improvements in open gas fires. October 29.  
13061 J. A. Yeaton and R. Middleton, Leeds. Improvements in machinery or apparatus for the manufacture of artificial fuel. October 30.  
13067 J. A. Yeaton and R. Middleton, Leeds. Improvements in machinery or apparatus for the manufacture of artificial fuel. October 30.  
13071 W. Armitage, Sheffield. Improvements in apparatus for smoke burning. October 30.  
13073 J. A. B. Bennett and G. E. Wright, King's Heath. Improvements in apparatus for mixing and burning gases. October 30.  
13164 S. A. Sadler, London. Improvements in the method of, and apparatus for, absorbing benzol or other hydrocarbon liquids into illuminating gas. October 31.  
13312 C. A. von Welsbach, London. A novel illuminating substance for incandescent gas burners. Complete specification. November 1.  
13360 C. Hunt, Westminster. Improvements in ascension pipes used in the manufacture of gas. November 1.  
13417 G. A. Sweetser, D. W. Bell, and W. Bohn, London. Improvements in the manufacture of candles and apparatus therefor. November 5.  
13530 T. A. Greene and C. M. Walker, London. Improvements in incandescent gas lamps. November 7.  
13560 R. Walker, Sunderland. Consuming oil as fuel. November 9.  
13567 G. Anderson, Spennymoor, Durham. An improved apparatus for the distribution of gas and air in regenerative steel-melting, glass-melting, and other furnaces wherein gaseous fuel is used for heating the same. November 9.  
13597 T. Rouet, London. The manufacture and employment of grease-proof cases for holding solid alcohols in stick, rod, or pellet form, as charge cartridges for easy insertion into alcohols lamps. November 9.  
13621 A. Wright, London. An improved manufacture of medicated candles, night-lights, lamp oils, and the like. November 10.  
13631 H. J. Allison, London.—Communicated by R. P. Ambler and H. Deitz, United States. Improvements in apparatus for making and burning gaseous fuel. Complete specification. November 10.  
13728 A. Gutensohn, London. An improved fire-lighter, suitable also for use as artificial fuel. November 11.  
13867 J. Rootes, London. Improved method and apparatus for rendering a liquid hydrocarbon gaseous. November 16.  
13890 D. W. Sugg, London. Improvements in apparatus for lighting by gas. November 16.  
13881 J. Ashworth, London. Improvements in means for utilising heat, consuming smoke, and economising fuel in furnaces. November 16.  
13883 J. Shaw and N. Arthur, Glasgow. Improvements in apparatus for feeding fuel to, and promoting draught and combustion in, furnaces. Complete specification. November 16.  
13990 J. G. Penn, London. Improvements in the manufacture of compound fuel. November 16.

- 12523 W. C. Stiff and H. B. S. Bennett, London. Improvements in the manufacture of tubes and ordnance of steel and iron. October 26
- 12524 J. E. Sherman, London. Improvements in the manufacture of iron and steel. October 27
- 12525 A. Watt, Battersea. Improvements in colouring metals. October 27
- 12526 S. Pitt, Sutton.—Communicated by J. Weirich, France. Improvements in the treatment of auriferous and auro-argentiferous minerals. October 27
- 12527 C. A. Faure, St. Brice, France. Improvements in the manufacture of the metals of the alkalis and alkaline earths. October 29
- 12528 E. Young, Dulwich. Improvements in the manufacture of iron and steel. November 3
- 12529 H. H. Johns, London. Improvements in tinning and finishing tin plates. Complete specification. November 3
- 12530 L. Kleinman, London. Improvements in furnaces for smelting zinc ores or other materials containing zinc, and in the mode of operating therewith. November 3
- 12531 W. Deighton, Sheffield. Improvements in furnaces, apparatus, and appliances connected therewith, for melting and treating ores, metals, and the like substances. Nov. 3
- 12532 W. H. Watson, Liverpool. Improvements in or relating to the treatment of certain substances containing alumina or iron, or both. November 3
- 12533 T. Davage, jun., London. An improved method of and apparatus for turning ingots of steel, iron, or other metals during the process of forging. November 4
- 12534 J. B. Sharp, London. Improvements in the manufacture of tubes of copper and of certain alloys of copper. Nov. 5
- 12535 J. A. Crane, Birmingham. Improvements in the production of iron and steel tubes. November 10
- 12536 L. Sargus, London. Certain improvements in apparatus for making moulds and cores of sand. Complete specification. November 10
- 12537 J. Riley and W. Crossley, Glasgow. Improvements in compound furnaces for making steel. November 10
- 12538 W. H. Lindsay, London. Improvements in the manufacture of corrugated plates of metal. November 11
- 12539 J. Pickering, Glasgow. Improvements in east steel forgings. November 13
- 12540 C. Cheary, London. Improved processes and apparatus for the treatment of ores. November 13
- 12541 W. R. Lake, London.—Communicated by MM. Denange et Sastre, France. An improved machine or press for the manufacture of lead pipe. November 14
- 12542 D. Davy and A. B. Baylis, London. Improvements in puddling and heating furnaces. November 14
- 12543 W. F. Richards, London. Improvements in the production of metallic zinc. November 16

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

- 12492 A. Twistleton Hall, London. Extracting oils from certain waste products. October 19
- 12522 J. Thomson, London. Obstetric soap. October 26
- 12523 T. J. Flynn, Manchester. Improvements in oxidising linseed-oil to be used in the manufacture of linoleum or other coverings for floors. November 1
- 12524 A. T. Hall, London. Improvements in refining vegetable oils. November 4
- 12525 G. W. Bremner, London. A new or improved method of treating materials for the manufacture of washing liquids and cleansing powders. November 14

## XII.—PAINTS, VARNISHES, AND RESINS.

- 12537 R. Morrin, Liverpool. New or improved coverings or coatings for propeller blades and other surfaces exposed to corrosive action. October 26
- 12538 W. R. Lake, London.—Communicated by L. Brown, United States. Improvements in and relating to the manufacture of pigments, paints, etc., from iron ore. Complete specification. October 29
- 12539 T. Childs, Huntington, and M. Chiapponi, London. An improved method of treating antimonial ores or compounds for the production of pigment. October 23
- 12540 J. C. Mewburn, London.—Communicated by J. L. Mariny et Cie, France. An improved manufacture of non-conducting material for covering steam-boilers, steam-pipes, hot or cold water pipes, and for other like purposes. Complete specification. October 24
- 12541 A. W. Anderson, London. Improvements in apparatus for facilitating the dissolution of oxide of lead and other substances for making lead salts for the manufacture of white lead and other compounds of lead. October 27
- 12542 J. Haylor, H. S. Read, and H. G. Pereival, London. Apparatus for the manufacture of white lead. October 30
- 12543 J. Pointon, Liverpool. Improvements in anti-rusting and anti-corrosive paints or compositions. October 31
- 12544 J. Beam, London. An improved method of treating iron ores, oxides of iron, and other like materials to be used in the manufacture of paints, colours, and the like. November 2
- 12545 E. Jackson, Liverpool. New or improved composition or paint, applicable for coating ships' bottoms and other structures. November 5
- 12546 A. Mackay and M. Mackay, London. Improvements in treating copal, kauri, sandrac, and other gum resins. November 6
- 12547 E. Edwards, London.—Communicated by M. Schauenberg, Belgium. An improved blacking. November 6

- 12548 G. W. Bremner, London. A new or improved method of operating on animal or mineral material for the manufacture of a paint suitable for ships' bottoms and other submerged bodies. November 13
- 12549 J. B. Freeman, London. An improved white pigment. November 13

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

- 12501 J. Nassie, jun., Glasgow. Improvements in operating the tables of leather-dressing and hide-working machines. October 30
- 12514 J. Nassie, jun., Glasgow. Improvements in leather-dressing and hide-working machines. October 31
- 12520 G. L. Peyre and C. Tissier, London. A process for tanning, currying, and finishing skins. November 3
- 12526 G. W. Bremner, London. A new or improved treatment of substances containing phosphoric acid and alumina for the manufacture of mineral gums and glue therefrom. November 13

## XV.—SUGAR, STARCH, GUMS, ETC.

- 12571 W. R. Lake (F. O. Matthieson). Improvements in and relating to bone-bone filters. Complete specification. Oct. 27
- 12574 W. R. Lake, London.—Communicated by F. O. Matthieson, United States. An improved process of and apparatus for the purification and decolourisation of sugar. Complete specification. October 27
- 12575 W. R. Lake, London.—Communicated by F. O. Matthieson and E. E. Quimby, United States. Improvements in apparatus for decolourisation of saccharine or other liquor. Complete specification. October 27
- 12576 W. R. Lake (F. O. Matthieson). Improvements in apparatus for the filtration of sugar liquor. Complete specification. October 27
- 12577 W. R. Lake (F. O. Matthieson). Improvements in and relating to bone-bone filters for filtering sugar liquor. Complete specification. October 27
- 12578 W. R. Lake (F. O. Matthieson). Improvements in apparatus for effecting the decolourisation of sugar liquor. Complete specification. October 27
- 12579 W. R. Lake (E. E. Quimby). Improvements in and relating to apparatus for effecting the decolourisation of sugar liquor. Complete specification. October 27
- 12592 A. Crum Ewing, Glasgow.—Communicated by T. Shields, British Guiana. A combined eliminator and filter for treating sugar-cane juice and other liquids. November 12

## XVI.—BREWING, WINES, SPIRITS, ETC.

- 12463 W. Stevens Squire, London. Improvements in the manufacture of yeast. October 19
- 12572 J. J. Cornish, London. Improvements in or applicable to tiles for forming the floors of malt and other kilns. Complete specification. October 22
- 12573 A. G. Clark, London.—Communicated by W. Thue, United States. An improved process of preserving brewers' and other grains. October 22
- 12574 A. F. Vuytske, London. Improved yeast press. October 24
- 12596 A. G. Fraser and G. Epstein, London. Improvements in the preparation of yeast. October 27
- 12599 A. G. Fraser and G. Epstein, London. Improvements in the purification of yeast. October 27
- 12590 E. Eggett, London. Yeast. October 28
- 12606 H. J. H. King, Newmarket. Improvements in automatically regulating the temperature of malt and hop kilns, and indicating the same. October 29
- 12603 A. G. Southby, London. Improvements in treating beer, and apparatus connected therewith. November 2
- 12617 A. G. Fraser and G. Epstein, London. Improvements in the treatment of distillers' worts, to separate yeast therefrom. November 2
- 12616 A. Z. Champy, A. N. Champy, and J. P. Champy, London. Improvement in the treatment of Jerusalem artichoke, to prepare it for use in distilling, the manufacture of glucose and sugar industries. November 3
- 12643 P. Robinson, London. Improvements in brewers' aerators, rousers, and mixers, suitable for fermenting vessels, and for other analogous purposes. November 10
- 12578 H. J. Hadden, London.—Communicated by C. Ross, Germany. Process for preventing the formation of deposit in Pasteurised beer. November 11
- 12582 J. R. Thame and T. Blake, London. An automatic heat indicator, for use in breweries and other places. Nov. 13

## XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

### (A) CHEMISTRY OF FOODS.

- 12454 A. Jones, London. Improvements in medicating saccharine and farinaceous substances ordinarily used as food. October 19
- 12497 H. C. Johnson, London. Process and apparatus for dehydrating, and refrigerating air for the transportation of meat, etc. October 27
- 12502 T. Dence and J. J. Mason, London. Improvements in the manufacture of artificially digested food. October 29
- 12573 M. Cisset, Paris. An improved process for preserving meat and like substances. November 3

## (B) SANITARY CHEMISTRY.

- 12188 W. Corry Dickenson, London. Improvements in filters for the purification of water, by the manufacture and employment of cartridges for charging and recharging filters. October 19.
- 12213 P. Parker, Keighley. Improvements in the construction of water filters. October 20.
- 12262 J. Greenwood, London. An automatic disinfecting apparatus. October 22.
- 12371 H. N. Collin, London. Improvements in the treatment and disposal of sewage. October 22.
- 12734 A. Gordon Salamon, London. Improvements in the manufacture of filtering materials. October 23.
- 12835 H. Fewson, Buckingham. Treatment of blood in slaughterhouses (public or private). October 27.
- 12851 W. H. Watson, Liverpool. Improvements in the treatment of sewage, dye-waters, or similar liquid refuse. November 3.
- 13123 A. Patrick, Glasgow. Improvements in earthenware pipes for sewage or other liquids. November 6.
- 13411 T. Archer, Junr., London. An improved means or apparatus for effecting the filtering or purifying of water on its passage from one place or vessel to another. November 7.
- 13587 A. A. Common, London. Improvements in the disposal of sewage. November 9.
- 13611 J. C. Kent, London. Improvements in and apparatus for automatically discharging any given quantity of disinfecting or other fluid into flushing tanks or other receptacles. November 10.
- 13660 W. C. Dickenson, London. Improvements in filters for the purification of water, which are instantly cleansed with filtered water without being taken to pieces. Nov. 10.
- 13719 W. C. Sillar and The Native Guano Co., London. Improvements in the treatment of sewage and other liquid or semi-liquid putrescent or putrescible matters. November 11.
- 13750 J. W. Slater and The Native Guano Co., London. Improvements in the preparation of agents to be used in the treatment of sewage and other liquid or semi-liquid putrescent or putrescible matters, and improvements in the treatment of such matters. November 11.
- 13761 G. W. Brenner, London. A new or improved treatment of chemical agents and the employment of the resultant for the precipitation, clarification, and defecation of sewage matters. November 11.

## (C) DISINFECTANTS.

- 12983 W. D. Borland, London. Obtaining granulated antiseptic preparations. October 23.

## XVIII.—ELECTRO-CHEMISTRY.

- 12378 A. Schanschiff, London. Improvements in galvanic batteries and in the preparation of liquids to be used in such batteries. October 16.
- 12128 O. Gee Pritchard, London. Improvements in the manufacture of carbons for electric arc lamps. October 17.
- 12515 A. W. Armstrong, Lewisham. Improvements in or connected with porous cells, sections, and plates for electrical purposes. October 20.
- 12562 J. Rettie and J. B. Garnham, London. Improvements in battery plates for electrical purposes. October 20.
- 12606 W. H. Scott and E. A. Paris, London. New or improved electrical apparatus for governing or regulating electric currents. October 21.
- 12721 J. Evelyn Liardet, London. Improvements in galvanic or primary batteries. October 23.
- 12906 A. Watt, Battersea. Improvements in the electrolytic colouration of metals. October 27.
- 12981 S. de Benardos and S. Olaszewski, London. An improved method of and apparatus for the working of metals and metalloids by the direct application of electric currents. October 28.
- 13026 A. Bernstein, London. Improvements in the manufacture of carbons for incandescence. October 29.
- 13207 E. Martin, London. An improved manufacture of metal wire for electrical transmission and other purposes. November 2.
- 13266 L. A. Groth, London. Communicated by R. Vogler, Germany. A new or improved dynamo electric machine. November 3.
- 13313 S. P. Thompson, London. Improvements in constant current dynamo electric machines. November 4.
- 13422 W. A. Barlow, London—Communicated by M. Sappey, France. A new or improved electric generator, with automatic field. November 5.
- 13514 E. G. Colton, London—Communicated by F. Haenichen, O. Haenichen, and O. Seebass, United States. Improved method of neutralising the residual magnetism in electro-magnets. Complete specification. November 6.
- 13639 W. Maxwell, London. Improvements in the manufacture of carbon filaments for incandescent lamps. November 10.
- 13651 G. Tolman and H. Denton, Wolverhampton. Improvements in dynamo electric machines. November 16.

## XIX.—PAPER, PASTEBOARD, &amp;c.

- 12510 F. G. Morton, and N. Salamon, London. Improvements in the manufacture of pulp, millboard, and brown paper, utilising certain waste materials. October 21.

- 12772 J. Raper Thame, London. Improvements in rendering paper and similar materials impervious to water, acids, and other liquids. October 21.
- 12846 N. Brown, London—Communicated by H. Pitzler, Germany. Improvements in machinery for making paste-board and for spreading adhesive and fluid or semi-fluid substances for other purposes. October 27.
- 13022 F. G. Morton, and N. Salamon, London. Improvements in the manufacture of pulp or "half-stuff," utilising waste or refuse materials. October 29.
- 13355 W. H. Akester and R. R. Kelly, London. Manufacture of material suitable as a substitute for cork. November 7.
- 13366 W. H. Akester and R. R. Kelly, London. Improvements in treatment of paper or other fabrics, textile or otherwise, with dissolved nitro-cellulose, adaptable for various purposes. November 7.
- 13629 A. R. O'Connor, London. Improvements in the preparation and treatment of paper and other pulps for the purpose of rendering the same waterproof. November 16.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

- 12813 J. Grossmann, Manchester. Improvements in or pertaining to the manufacture of prussic acid and its compounds. November 13.

## XXI.—EXPLOSIVES, MATCHES, &amp;c.

- 12450 F. W. Titchhurst, Birmingham. A new or improved instrument or apparatus for determining and indicating the comparative strength of powder charges. October 19.
- 12775 O. Inray, London—Communicated by R. Bernstein, Germany. Manufacture of granular nitro-cellulose. October 21.
- 12857 H. Inray, London—Communicated by H. Dulitz, Germany. Manufacture of an explosive compound. October 26.
- 13581 B. H. Remmers and J. Williamson, Glasgow. An improved manufacture of gunpowder. November 9.
- 13582 E. H. Remmers and J. Williamson, Glasgow. Improvements in the manufacture of gunpowder, and in the treatment or preparation of carbonaceous materials therefor. November 9.
- 13290 H. H. Lake, London—Communicated by C. Lunn, Sweden. An improved explosive compound. November 10.
- 13338 R. Bell, London. An improvement in wax matches and vesta-fusces. November 11.

## XXII.—ANALYTICAL CHEMISTRY.

- 13050 F. Lux, London. An improved method of ascertaining the specific gravity, the pressure, and the component parts of fluids. Complete specification. October 29.

## ENGLISH PATENTS PUBLISHED.\*

APPLIED FOR DURING 1884 AND 1885.

## I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

1881.

- 16031 W. A. M. Valon and W. G. Hicks. Improvements in retort lids and fastenings. 6d.
- 16338 S. Pitt—Communicated by R. P. Pictet. Refrigerating apparatus. 6d.
- 16588 C. J. Dunn. Lagging or covering steam boilers, etc., to prevent radiation of heat; also covering steam pipes, refrigerators, etc., to exclude heat or cold. 6d.
- 16713 E. Perrett. Apparatus for effecting the subsidence of solid matters in suspension in liquids. 8d.

## II.—FUEL, GAS, AND LIGHT.

1884.

- 15127 E. Biederman and E. W. Harvey. Utilising waste or other gaseous products of combustion. 6d.
- 15310 A. K. Huntington. Separation of carbonic oxides from the products of furnaces or gas producers. 2d.
- 15317 J. Moore. Apparatus for utilisation of waste heat and combustion of smoke in furnaces, &c. 6d.
- 15357 W. H. Westwood and E. F. Wright. Improvements in lids or doors for gas retorts, &c. 6d.

\* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 5s.	5d.
Above 5s., and not exceeding 15s.	1d.
" 15s. 6d., " " 25s. 6d.	1d.
" 25s. 6d., " " 35s. 6d.	2d.

- 16164 W. R. Hodgkinson. Apparatus and materials employed in producing self-igniting luminous gas for signalling purposes. 6d

 8410 E. W. Parnell and J. Simpson. Obtaining sulphuretted hydrogen from sulphide of ammonium. 4d

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

1884.

- 16519 A. Hentschel and J. V. E. Taylor. Means or apparatus for printing or stamping designs, etc., in colours, oils, or acids, on vitreous, earthen, or other ware. Partly communicated by Messrs. A. L. Damkohlers and C. Weber. 6d

1885.

- 1448 J. G. Muller. Manufacture of tiles and other objects in imitation of majolica ware. 2d

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

1884.

- 14393 J. Stansfield. Manufacture and laying of asphalt. 4d  
 15759 W. G. Margetto. Manufacture of Portland cement, and apparatus therefor. 8d  
 16393 J. Gillespie. Improvements in bricks and the internal walls of furnaces, and in concrete walls. 6d  
 16360 W. Smith. The manufacture of Portland cement. 2d

## X.—METALLURGY, MINING, ETC.

1884.

- 13929 W. A. and C. A. Biddell. Manufacture and treatment of iron and steel, the coating of such, and introduction of vitreous and other matter. 6d  
 13460 T. Vosper and J. Eastcott. Apparatus for cleansing and separating metallic ores, especially those of tin, lead, and gold. 6d

- 14330 R. Stone. Improvements in smelting, and in apparatus connected therewith. 2d  
 16019 R. Hatfield. Manufacture and treatment of self-hardening steel. 4d  
 16671 E. S. and S. Thompson. Covers and dishes for close annealing iron, steel, and other metals. 6d  
 16855 F. M. Banks. Method of plating silver with gold. 4d  
 16857 T. Bowen. The purification of tin and its alloys, and apparatus therefor. 6d

1885.

- 16931 L. A. Groth—Communicated by D. Mindeleff. Method and apparatus for extracting nickel and cobalt from ores containing them. 6d  
 18416 C. B. Holland. Annealing thin sheets of iron and steel, and furnaces suitable to be employed therein. 6d  
 16940 A. J. Boulton—Communicated by H. M. Pierce. Reducing ores, and obtaining metal therefrom by the utilisation of waste gases from carbonisation of vegetable matter. 4d

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

1884.

- 11700 W. P. Thompson—Communicated by M. Julien and M. Blumski. Distillation of fatty substances by means of superheated steam, and apparatus therefor. 6d  
 16817 F. J. Harrison. An improved cleansing compound. 2d

## XII.—PAINTS, VARNISHES, AND RESINS.

1885.

- 312 J. S. Gisborne. Anti-fouling and preservative composition or paint for coating ships' bottoms, etc. 4d  
 9414 W. Macrone. Manufacture of dry colours. 2d  
 9413 W. Macrone. A new or improved varnish or size. 2d  
 9419 T. Harrison. Coating the insides or out-sides of iron and steel ships, etc., where the preservation of iron, steel, or other metal is desirable. 2d

## XIV.—AGRICULTURE, MANURES, ETC.

1885.

- 5227 C. Lehofer. Treatment of human excrements, sewage and similar matter for the manufacture of manure. 6d

## XV.—SUGAR, STARCHES, GUMS, ETC.

1885.

- 4948 W. R. Lake—Communicated by W. T. Jebb. Improved starch-meal. 6d  
 1664 W. R. Lake—Communicated by W. T. Jebb. Improvements in the manufacture of starch-meal. 6d  
 10172 P. Jensen—Communicated by M. C. P. Barbe. Manufacture of refined sugar, and apparatus therefor. 6d

## XVI.—BREWING, WINES AND SPIRITS.

1884.

- 16043 E. T. Pemberton. Brewing or producing ale and porter. 4d

## XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

## (B) SANITARY CHEMISTRY.

1884.

- 16705 A. Howatson. Apparatus for treating water with lime or other matter for the purpose of purifying the said water. 6d  
 16706 A. Howatson. Apparatus for separating solid impurities from water or other liquid. 8d

1885.

- 7352 B. L. Ryder. Method and apparatus for desiccating vegetable and animal matter. 6d

## (C) DISINFECTANTS.

1881.

- 16427 J. Jeyes. An improved disinfecting compound. 4d

## XVIII.—ELECTRO-CHEMISTRY.

1884.

16554 A. M. Clark—Communicated by P. Moebius. Apparatus and process for the electrolytical separation and deposition of metals. 10d

## XIX.—PAPER, PASTEBOARD, Etc.

1885.

9319 H. W. Morrow. Treatment of paper and other fibrous material. 6d  
 9411 W. Macrone. Waterproofing paper, etc., and machinery therefor. 4d  
 9412 W. Macrone. Machinery for varnishing or sizing and applying colours to paper and other fabrics. 6d

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

1885.

11258 D. D. Cattinach. Method and apparatus for the manufacture, distillation, and concentration of alcohol, hydrocarbons, and acetic acids. 8d

## XXI.—EXPLOSIVES, MATCHES, Etc.

1884.

W. Virtue, 10 Glasgow; Königl. Landwirtschaftlichen Schule, Weihenstephan, Bavaria.

## LIST OF MEMBERS ELECTED, DECEMBER 23rd, 1885.

Frank Bishop, 6, Holly Terrace, West Hill, Highgate, photographic chemical manufacturer.  
Oswald D. Cottell, 101, Long Lane, Bermondsey, S.E., vinegar manufacturer.  
Francis J. H. Coutts, 61, East View, Turlton Road, near Bolton, chemical bleach works.  
Percy R. Crompton, Dearden's House, Bury, Lancashire, paper manufacturer and chemist.  
Chas. Deakin, Egerton, near Bolton, Lancashire, dyer.  
Wallace Fairweather, 133 Buchanan Street, Glasgow, engineer and patent agent.  
Jno. Hatfield, Windsor Road, Newton Heath, Lancashire, bleacher and dyer.  
C. T. Heycock, M.A., King's College, Cambridge, lecturer on chemistry.  
Z. George Heys, Springhill Villa, Burnhead, near Glasgow, calico printer.  
Harold Imray, Lomnay, East End Road, Finchley, N., patent agent.  
F. W. T. Krohn, 13, Belsize Square, South Hampstead, N.W., chemist.  
J. T. Leon, 26, Belsize Park Gardens, South Hampstead, N.W., chemist.  
Alf. Lundberg, Bergvik, Sweden, chemical engineer to wood pulp works.  
H. Forster Morley, University Hall, Gordon Square, W.C., assistant professor of chemistry.  
E. Perrett, 8, Victoria Chambers, Westminster, S.W., civil engineer.  
Fred. W. Shaw, Heapey Bleach Works, near Chorley, analyst.  
John Shaw, Bradley Mills, Halifax, paper maker.  
E. Snelling, 5, Spital Square, Bishopsgate Street, E., brewer.

## Death.

Nov. 26, Alfred Tribe, 14, Denbigh Road, Bayswater, W.

ERRATUM.—On page 575, left column, line 23, insert the words "a large bottle" after the word "chamber."

MEETINGS, SESSION 1885-86.—First Monday in each month (unless otherwise indicated).

### ORDINARY MEETINGS.

First Monday in the Month, at 8 p.m.

January 1, 1886.—Mr. G. E. Davis, F.I.C.—"On the Enrichment of Coal Gas by certain Hydrocarbons." Mr. C. T. Kinzett—"Notes on Russian Turpentine."

February 1.—Mr. Gustav Bischof—"Notes on Dr. Koch's Water Test." Mr. J. W. Westmorland, A.R.S.M.—"The Estimation and Valuation of Copper Ores and Products for Commercial Purposes."

March 1.—Mr. Bayerton Redwood, F.I.C.—"Viscosimetry." Mr. T. B. Lightfoot, M.I.C.E., M.I.M.E.—"Ice Making and Cooling Machinery."

April 5.—Professor Unwin, M.I.C.E.—"The Principles and Methods of Testing Cementing Materials."

May 3.—Messrs. Macnao and Beckett—"The Treatment of Water for Technical Purposes."

June 7.—Dr. Meymott Tidy—"Chemical Treatment of Sewage."

July.—Annual Meeting at Liverpool.  
Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held Monday, December 7, 1885.

PROF. ARMSTRONG IN THE CHAIR.

## NEW ASPECTS OF FILTRATION AND OTHER METHODS OF WATER TREATMENT; THE GELATINE PROCESS OF WATER EXAMINATION.

BY PERCY F. FRANKLAND, F.I.D., B.Sc., F.C.S., F.I.C.,  
Associate of the Royal School of Mines.

UNTIL recently our definite knowledge of the value of filtration and other methods of water purification has been almost exclusively limited to an acquaintance with the chemical improvement which these processes are capable of effecting. This knowledge, although of the greatest importance in judging of their value, only constitutes a part, and not the whole of the information which it is desirable to acquire with regard to these processes. For, since the communication of some diseases by means of living organisms has ceased to be a theory, but has become a well-established fact, resting upon the surest foundation, it has been felt that the question of water treatment must be considered from a biological as well as from a chemical point of view. This necessity has for a long time been felt by no one more strongly than by

chemists, who have devoted much attention to water and its purification, and it has been only in consequence of the want of reliable means by which the investigation could be prosecuted from this point of view that but little progress has been made in this study. It is true that methods have from time to time been devised for the biological examination of waters, but these have been so unreliable that they have failed to satisfy the exact quantitative requirements of the chemist. These methods having been generally invented by chemists themselves, they have not sufficiently taken into consideration the habits and necessities of life of those organised forms which they were intended to discover. In illustration of this I need only remind you of the ingenious method of examining waters devised more than ten years ago by Mr. Heisch. For the purpose of determining the presence of organised matter in water, Mr. Heisch added to a given quantity of the water under examination, a certain proportion of sugar, and observing that a marked difference was exhibited by waters of various origin in the production of vegetable growths subsequent to this addition, he argued that those waters which yielded an abundance of such growths were richer in organic life than those which yielded less. Mr. Heisch, however, did not bear in mind that sugar and water are not in themselves sufficient for the maintenance of plant life, but that other substances, and notably phosphates, are requisite, so that the greater or less abundance of growths in his experiments was due not to the presence or absence of living matters in the original water, but to the presence or absence of these accessory food-substances amongst the mineral constituents of the water. In point of fact, Mr. Heisch's process was found to constitute an admirable test for phosphoric acid, whilst as a means of ascertaining the biological character of waters, it was wholly unreliable. Other methods, based upon similar conceptions, but also tainted with the same fundamental error, have made their appearance since, although, as far as I am aware, they are not in actual, or at any rate extensive, use by persons engaged in water examination.

I have the honour of bringing before the Society this evening a method of examining waters biologically, upon the study of which I have been engaged for some years past, and the authorship of which is due to Dr. Koch of Berlin. This method is an adaptation, for the purposes of water examination, of a more general mode of biological investigation which has been long practised by Dr. Koch—viz., the cultivation of lower forms of life in a solid medium. The great advantage which the use of a solid medium affords, is that the micro-organisms imported into this medium grow and multiply on the spot where they have been first planted, being restricted from undergoing any movement of translation, such as necessarily takes place in a fluid. In consequence of this restriction, the progeny of each organism gathers round the parental home and forms a colony, which, rapidly increasing in size, soon becomes visible to the naked eye, the appearance of the colony being in many cases distinctive of the particular organisms of which it is composed.

It is necessary, of course, that this solid medium, into which the organisms under examination are imported, should furnish all the materials necessary for their growth and development. The medium recommended by Dr. Koch for this purpose, has the following composition:—

Lean Meat .....	1 lb.
Gelatine .....	100 grms.
Peptone (solid) .....	10 "
Common Salt .....	1 "
Distilled Water .....	1 litre.

This is also the composition of the solid nutritive medium used by me in my earlier experiments, but during the summer months I found that it became liquid at an inconveniently low temperature (about 20° C.), so that I raised the proportion of gelatine to 150grms. per litre, to which proportion I still adhere. The mixture is prepared as follows:—

The meat is finely minced and infused with  $\frac{1}{2}$  litre of cold distilled water, for one to two hours, the solid part being then strained off through linen. The gelatine is allowed to soak in the other  $\frac{1}{2}$  litre of water, and to this the extract of meat is added. The whole is now heated until the complete solution of the gelatine has taken place, the peptone and salt being then added and allowed to dissolve. This liquid exhibits a distinctly acid reaction, which must be carefully neutralised by means of carbonate of soda. The neu-

purpose, and the construction of which is shown in the accompanying figure.

Tubes prepared and sterilised in this manner, I have found to remain unchanged for an indefinite period of time.

#### COLLECTION OF SAMPLES OF WATER.

The water for examination is collected either in flasks plugged with cotton wool, or in accurately stoppered bottles; but in either case these vessels and their stoppers must be carefully sterilised by heating in an air-bath to 150—180° C., for at least three hours. If cotton-wool stoppers are used, care must be taken that the collected water does not come in contact with the wool, and as this is unavoidable when the samples have to be conveyed any distance, I prefer collecting them in

FIG. 1.—STEAM STERILISER.

tralised liquid is then clarified by beating into it the contents of two or three eggs, along with the broken shells, the whole being briskly boiled for a few minutes. The coagulated albumen rises to the surface, and carries with it the other solid particles suspended in the liquid. On then straining through linen, a fairly clear liquid is obtained, which is finally clarified by passing through filter-paper placed in a funnel provided with a hot-water jacket, the filtrate being rejected until it runs perfectly clear and limpid. The filtrate sets, on cooling, to a yellowish-brown transparent jelly. Whilst still liquid it is poured into clean test-tubes, the quantity which I employ in each tube being exactly 7cc. The test-tubes are tightly plugged with cotton wool, and then at once sterilised by steaming them for half-an-hour, on three consecutive days, in a vessel made expressly for the

glass-stoppered bottles, of about 70cc. capacity: these are carefully cleaned and rinsed with distilled water; they are then dried, and the stoppers firmly screwed in, and each bottle is put into a small tin canister, which I have had made for the purpose. These canisters, with their contained bottles, are then packed into an air-bath, which is heated to 150—180° C., for at least three hours. The bottles thus sterilised can be easily transported without suffering contamination by dust to the place where the sample is to be collected. In the actual collection of the sample much care and judgment has to be used, so as to avoid the introduction of accidental sources of contamination. The outside of the bottle should be rinsed in the water before removing the stopper, and when the bottle is opened the water is at once allowed to enter, and fill the bottle to the extent of four-fifths, the stopper

being immediately replaced and tightly screwed in, so that the exposure to the air is reduced to a minimum. The bottle is replaced in the tin canister, and the lid closed. In collecting samples of water from rivers, reservoirs, lakes or ponds, I do not, if possible, remove the stopper until the bottle is completely immersed in the water, and replace it while still beneath the surface.

The sample thus collected should be submitted to examination, without delay, on the same day, if possible; and during any unavoidable interval it should be kept cool.

#### EXAMINATION OF THE SAMPLE.

Immediately before examination the sample must be violently shaken to ensure an even distribution of the organisms throughout the water, and for this purpose stoppered bottles present a great advantage over plugged flasks. The stopper is now carefully removed, and a sterilised pipette\* introduced into the water. At the same time, a tube of the sterilised gelatine-peptone medium, which I melt by placing

FIG. 2.

the tube in a water-bath not heated above 30° C., is opened after first burning the external portion of the cotton-wool plug in a Bunsen flame. Into the open tube a definite number of drops† of water are delivered from the pipette, the water and gelatine are rapidly mixed by agitation in the tube, which is held in a slanting position to prevent the entrance of dust. The fluid mixture of gelatine and water is then at

FIG. 3.

once poured on to a clean sterilised photographic plate, resting in a perfectly horizontal position, and this is then immediately covered by a glass shade. The arrangement of the shade and plate are shown in the accompanying figures (2, 3, and 4), which also illustrate the gradual process of evolution which this important part of the apparatus has undergone in the course of my experiments.

Originally two flat glass dishes fitting into each other were employed, and in the under one (the smaller of the two) a glass tripod supporting a glass plate was placed, as well as a little mercuric chloride solution (2 per cent. strength) at the bottom to maintain a moist atmosphere in the interior. The interior of the dishes was thus in direct communication, by a

circuitous path it is true, with the outer air. To obviate this, I soon placed the dishes in a shallow porcelain tray, such as is used in photography, and into this tray a 2 per cent. solution of mercuric chloride was poured so as to form an antiseptic seal between the outer and inner air. More recently still, I have done away with the under dish altogether, and the tripod now simply stands in a common soup-plate, into which the solution of mercuric chloride is poured until the communication between the internal and external air is cut off, the mercuric chloride solution thus serving the double purpose of an antiseptic seal, and of maintaining the moisture of the internal air. By thus simplifying the apparatus, I have reduced the cost from about fifteen shillings to fifteen pence, a difference which is of no little consequence, as in

FIG. 4.

carrying out an extensive series of experiments it is necessary to have from two to three dozen of these dishes at one's disposal; whilst by the introduction of the antiseptic seal, the plates may be allowed to stand for an indefinite period of time without the possibility of aerial contamination. The sterilisation of these dishes, tripods, etc., is effected by rinsing them with the 2 per cent. solution of mercuric chloride immediately before use. They are then placed on a 3-screw levelling stand, and the glass plate resting on the tripod is rendered perfectly horizontal by means of a spirit-level. The sterilised glass plate, which is to receive the gelatine, is now carefully withdrawn

FIG. 5.

from the metal box (Fig 5), in which it has been sterilised, the future upper surface being held downwards during the transfer. As soon as it is placed on the levelled plate, the glass dish is put over it only to be momentarily again raised when the mixture of gelatine and water is poured on to the plate as already described. These operations are carried on in a room, the temperature of which is kept as low as possible, so as to accelerate the setting of the gelatine, which generally takes place in the course of a few minutes. It is also essential that in this room all sources of dust be rigorously excluded, and the table on which I operate has a glass top, and this is washed with mercuric chloride solution immediately before use.

As soon as the gelatine has set on the plate, it is at once removed in its dish from the levelling table and placed in a chamber maintained at a temperature of 20—25° C. for incubation.

The period of incubation generally varies from 3 to 5 days, but sometimes it is continued for a longer period of time to make sure that all the organisms present have had a due opportunity of development.

The gelatine plates are daily inspected during the period of incubation, without removing the glass cover, so that the progress of the colonies derived from the individual organisms may be watched;

\* The pipettes are sterilised in a tin box by heating to 150—180° C. for at least three hours.

† The volume of the drops delivered by each pipette is carefully determined by previous experiment.

when these have reached such dimensions that they are distinctly visible to the naked eye, and before the contours of different colonies have begun to coalesce, the plates are withdrawn for examination. For this purpose the plate is placed upon a second glass plate of about the same size, the latter being ruled in squares and placed upon a black ground. The colonies are counted with the aid of a strong hand-lens, the more doubtful ones being further examined by means of a simple microscope. In order to arrive at an accurate conclusion with respect to the number of colonies, it is necessary that they should be all counted individually, but in cases in which the colonies are too numerous for this, an estimate of the total number may be formed by counting those present in a few of the squares, and then multiplying accordingly; this method should, however, only be resorted to in cases of absolute necessity, as the result obtained is very much less trustworthy.

If the precautions here described are rigidly, and above all intelligently, observed, little or no aerial contamination can take place in a reasonably pure atmosphere. Thus I have made a large number of experiments using boiled distilled water, and have found that almost invariably the plates remain absolutely unchanged, whilst only in most exceptional cases does any colony whatsoever make its appearance on the plate. Thus of twelve plates put up with sterilised water a week ago, no colonies made their appearance, excepting a mould on one plate. In this respect my results compare favourably with those of Dr. Koch, who finds that three colonies is the average obtained with sterilised water; now this difference may be partly due to my experiments being performed in an atmosphere which is essentially inimical to organic life—viz., that of a chemical laboratory,—whilst it is also doubtless due to the use of my mercuric chloride seal, as well as to the greater general purity of the atmosphere in English buildings. This point has long since been illustrated in connection with surgery, for Sir Joseph Lister's antiseptic treatment of wounds was eagerly adopted on the Continent, whilst it found for some time but scant favour in this country, this being due to the comparatively excellent results which had been already obtained by English surgeons, whilst on the Continent the major operations of surgery were previously attended with an excessive percentage mortality in consequence of the greater abundance of septic organisms.

#### PRACTICAL APPLICATION OF GELATINE PROCESS.

It is obvious that the process of water-examination just described enables us to investigate the subject of water-purification from an entirely novel point of view. By determining the number of micro-organisms present in water before and after any process of purification, we are able to obtain for the first time complete and reliable information as to the value of such a process in removing micro-organisms. Such information is, of course, of immense importance in the case of the purification of waters which are liable to dangerous contamination by organised poisons, and constitutes an invaluable supplement to the results of chemical examination.

With the aid of this process I have carried out a large number of experiments on the efficiency of various methods of water-treatment in removing living matter. The processes which I have submitted to examination may be divided into three classes:—

1. Purification by Filtration.
2. " " Agitation with Solid Particles.
3. " " Chemical Precipitation.
4. " " Natural Agencies.

#### I.—PURIFICATION BY FILTRATION.

Although it has been long known that some filtering materials, when judiciously applied, are capable of depriving water of all the organisms that it may contain; yet, until the method of gelatine culture was adopted, there was no readily available means by which the relative efficiency of different filtering materials could be estimated on a quantitative basis.

I have submitted to examination, as regards their efficiency in this respect, a number of filtering materials, employing in nearly all cases equal thicknesses of the various substances which were prepared in the same state of division. The filtering stratum was constructed exactly 6 inches in depth, and the filtering material was, with a few exceptions, made to pass through a sieve of 40 meshes to the linear inch. The results obtained in these experiments, the earlier of which were communicated to the Royal Society in June last, may be briefly stated as follows:

##### FERRUGINOUS GREENSAND (from Redhill, Surrey).

###### Initial efficiency:—

Unfiltered water.....	80 organisms per cc.
Filtered do.....	0 " "
Reduction = 100 per cent.	

###### Efficiency after 13 days' action:—

Unfiltered water.....	8000 organisms per cc.
Filtered do.....	1000 " "
Reduction = 88 per cent.	
Rate = '35 litre per 24 hours.	

###### Efficiency after 1 month's action:—

Unfiltered water.....	1250 organisms per cc.
Filtered do.....	780 " "
Reduction = 39 per cent.	
Rate = '86 litre per 24 hours.	

##### ANIMAL CHARCOAL.

###### Initial efficiency:—

Unfiltered water ..	Organisms too numerous to count.
Filtered do.....	0 organisms per cc.
Reduction = 100 per cent.	

###### Efficiency after 12 days' action:—

Unfiltered water.....	2800 organisms per cc.
Filtered do.....	0 " "
Reduction = 100 per cent.	
Rate = '35 litre per 24 hours.	

###### Efficiency after 1 month's action:—

Unfiltered water.....	1250 organisms per cc.
Filtered do.....	7000 " "
Increase = 117 per cent.	
Rate = '65 litre per 24 hours.	

##### IRON—SPONGE.

###### Initial efficiency:—

Unfiltered water.....	80 organisms per cc.
Filtered do.....	0 " "
Reduction = 100 per cent.	

###### Efficiency after 12 days' action:—

Unfiltered water.....	2800 organisms per cc.
Filtered do.....	0 " "
Reduction = 100 per cent.	
Rate = '30 litre per 24 hours.	

###### Efficiency after 1 month's action:—

Unfiltered water.....	1250 organisms per cc.
Filtered do.....	2 " "
Reduction = 99.8 per cent.	
Rate = '31 litre per 24 hours.	

##### BRICKDUST. (Pulverised Red Brick).

###### Initial efficiency:—

Unfiltered water.....	3000 organisms per cc.
Filtered do.....	730 " "
Reduction = 76 per cent.	

###### Efficiency after 5 weeks' action:—

Unfiltered water.....	6000 organisms per cc.
Filtered do.....	400 " "
Reduction = 93 per cent.	
Rate = '36 litre per 24 hours.	

## COKE.

*Initial efficiency:—*

Unfiltered water.....	3000 organisms per cc.
Filtered do.....	0 " "
Reduction =	100 per cent. " "

*Efficiency after 5 weeks' action:—*

Unfiltered water.....	6000 organisms per cc.
Filtered do.....	30 " "
Reduction =	98.5 per cent. " "
Rate =	38 litre per 24 hours.

I have made further experiments in conjunction with my assistant, Mr. A. W. Bishop, on the efficiency of this filtering material. In these experiments the filters employed were of similar construction to those already described, but an aqueous extract of garden soil was employed instead of urine-water. Two filters (a) and (b) were submitted to examination, under conditions as similar as possible:—

*Initial efficiency (2nd day):—*

	Unfiltered Water	Filter (a)	Filter (b)
Organisms in 1cc. ....	26,000	none	none
Reduction .....	100	100	100
Rate of filtration (in litres per 24 hours).....	0.67	0.67	0.51

*After 5 weeks' action (21st day):—*

	Unfiltered Water	Filter (a)	Filter (b)
Organisms in 1cc. ....	2,250	339	219
Reduction .....	85	90	90
Rate of filtration (in litres per 24 hours).....	1.00	0.78	0.78

On comparing these latter experiments with those previously obtained, it will be seen that although the initial efficiency was in both cases the same, the greater rate of filtration which prevailed in the latter experiments caused the efficiency to deteriorate more rapidly, the filter (a), which was the most rapid breaking down to a greater extent than the less rapid filter (b).

The unfiltered and filtered waters respectively were also submitted to chemical examination, at the time that the filters were exerting their greatest efficiency in the removal of micro-organisms; the results are given in the following table, together with those obtained by the filtration of the same water through fine vegetable charcoal, and through a mixture of fine and coarse vegetable charcoal respectively:—

RESULTS OF ANALYSIS EXPRESSED IN PARTS PER 100,000.

	Unfiltered Water.	Water from fine Coke.		Water from	
		(a)	(b)	Fine Wood Charcoal.	Fine and Coarse Wood Charcoal.
Total Solids .....	21.80	21.60	25.00	24.68	24.61
Organic Carbon.....	144	118	107	090	098
.. Nitrogen.....	050	040	038	024	031
Ammonia .....	0	0	0	0	0
Nitrogen as Nitrates and Nitrites.....	199	209	202	221	217
Total combined Nitrogen .....	240	249	240	245	248
Chlorine .....	1.9	1.9	1.9	1.9	1.9
HAZINESS. { Temporary .....	11.3	11.3	11.3	12.5	12.3
Permanent .....	5.6	5.6	5.6	4.6	4.6
Total.....	16.9	16.9	16.9	17.1	16.9

These results show that filtration through coke exerts but an insignificant chemical action, even when the purification from a biological point of view is complete.

## VEGETABLE CHARCOAL.

The very favourable results obtained with coke led me to investigate the filtering power of the still more

porous vegetable or wood charcoal. This material was also passed through the same sieve and employed in filters of similar construction. In the first experiment urine-water was used, with the following results:—

*Initial efficiency (2nd day):—*

Unfiltered water.....	9700 organisms per cc.
Water filtered through fine charcoal ..	0 " "
Reduction =	100 per cent.

Later experiments were made with an aqueous extract of soil, the following results being obtained:—

*Initial efficiency (2nd day):—*

Unfiltered water.....	2858 organisms per cc.
After filtration through fine wood charcoal .....	0 " "
Reduction =	100 per cent.
Rate of filtration .....	0.17 litre per 24 hours.

*After one month's action (29th day):—*

Unfiltered water.....	2220 organisms per cc.
After filtration through wood charcoal ..	107 " "
Reduction =	95 per cent.
Rate of filtration .....	0.17 litre per 24 hours.

It is thus seen that the efficiency of the fine charcoal at the end of one month is less than that of the coke with the slow rate of filtration, but greater than that of the more rapid coke filters at the end of three weeks, the rate of filtration in the case of the charcoal being markedly less than in any of the coke experiments.

In order to obtain a more rapid charcoal filter, an intimate mixture was made of equal parts of coarse and fine charcoal (the former having passed through a sieve 9 × 30 meshes, and the latter through one 40 meshes to the linear inch), and this introduced into a glass tube, so as to form a stratum of filtering material 6 inches in depth. With this filter the following results were obtained:—

*Initial efficiency (2nd day):—*

Unfiltered water.....	26,000 organisms per cc.
Filtered through coarse and fine charcoal.....	0 " "
Reduction =	100 per cent.
Rate of filtration .....	0.20 litre per 24 hours.

*After three weeks' action (21st day):—*

Unfiltered water.....	2920 organisms per cc.
Filtered through coarse and fine charcoal ..	506 " "
Reduction =	77 per cent.
Rate of filtration .....	0.45 litre per 24 hours

Thus with wood charcoal, when the rate of filtration approaches that through coke, the improvement, from a biological point of view, is markedly less.

The effect which this material has upon the chemical composition of the water, as exhibited in the above table, is greater than that of coke, but also not very considerable.

It has generally been supposed that most filtering materials offer little or no barrier to micro-organisms, and that the latter are capable of passing without sensible obstruction through the pores of filters containing pulverised materials. These experiments, however, show that it is extremely simple to construct filters which shall possess the power of removing micro-organisms, in the first instance at least. This power is, moreover, possessed by substances which exercise scarcely any chemical action on the organic matter present in the water—*e.g.*, coke, vegetable charcoal, and biscuit porcelain, as well as by those which reduce both the organic and mineral ingredients of the water to a very marked extent, like animal charcoal and iron.

Especially noticeable is the case of vegetable carbon, whether in the form of charcoal or coke; this material has been generally regarded as of but little value for water purification, owing to its chemical inactivity; but as biological filters, we see that these substances occupy a very high place, and, owing to their cheapness and the facility with which they may be renewed and profitably disposed of as fuel, they are in my opinion destined to be of great service in the purification of water. These materials, coke and vegetable charcoal, are also specially well fitted for use in breweries and distilleries, where it is so necessary to have a water which, though perfectly free from organic life, is at the same time free from antiseptic substances, such as iron, which militate against fermentation. Coke has already been used in this capacity, at my suggestion, with marked success.

My experiments, however, show most distinctly the necessity of frequent renewal even in the case of the best filtering materials, and this is a point which, unfortunately, is too often lost sight of—the idea that “once a filter always a filter,” being erroneous in the extreme.

Lastly, we have abundant confirmation of the principle which has long been known to water engineers—*viz.*, that what is gained in rapidity is lost in efficiency, and *vice versa*.

## II.—PURIFICATION BY AGITATION WITH SOLID PARTICLES.

It appeared probable, from the results of the filtration experiments already described, that organised matter might be largely removed by mere contact with finely divided matter. A series of experiments was consequently undertaken with a view to ascertaining to what extent this was the case, and in some instances the reduction was found to be very much greater than could have reasonably been anticipated.

In these experiments water containing micro-organisms was shaken up for a definite length of time with a given quantity of the finely divided matter, which was used in the same state of subdivision as in the filters already described. The water was then allowed to subside and the clarified water submitted to examination *as soon as possible* after complete subsidence had taken place, as I argued that, if the organisms were simply carried to the bottom by the subsiding particles without suffering any injury, they would rapidly again become distributed through the upper layers of water by multiplication. This supposition has been amply verified by experiment.

### AGITATION WITH SPONGY IRON.

The water was shaken with one-tenth of its weight of this material for one minute in one case, and for fifteen minutes in another. In each case the water was allowed to subside for half-an-hour before examination.

Untreated water contained	609 organisms per cc.
After 1 minute's agitation	28     "     "
Reduction	= 95 per cent.
After 15 minutes' agitation	63 organisms per cc.
Reduction	= 90 per cent.

On another occasion the water of the Thames at Hampton was shaken with spongy iron for fifteen minutes with the following result:—

Thames water	155 organisms per cc.
after 15 minutes' agitation	10     "     "
Reduction	= 93 per cent.

### AGITATION WITH CHALK.

Urine-water was shaken for fifteen minutes with one-fiftieth of its weight of chalk, and then allowed to subside for five hours:—

Untreated water	8000 organisms per cc.
Ditto after agitation	270     "     "
Reduction	= 97 per cent.

### AGITATION WITH ANIMAL CHARCOAL.

Urine-water was shaken with one-fiftieth of its weight of animal charcoal for fifteen minutes, and then allowed to subside for nearly five hours:—

Untreated water	8000 organisms per cc.
Ditto after agitation	60     "     "
Reduction	= 99 per cent.

### AGITATION WITH VEGETABLE CHARCOAL.

Water containing soil-extract was shaken with one-fiftieth of its weight of ordinary wood charcoal for fifteen minutes, and was then allowed to subside for twenty-seven hours:—

Untreated water	3000 organisms per cc.
Ditto after agitation	120     "     "
Reduction	= 96 per cent.

### AGITATION WITH COKE.

Urine-water was shaken with one-fiftieth of its weight of fine coke for fifteen minutes, and then allowed to subside for forty-eight hours:—

Untreated water	Too numerous to be counted.
After agitation with coke	None.
Reduction	= 100 per cent.

Further experiments made with water containing soil-extract have shown that this process of purification is unreliable, owing apparently to the numerous conditions which are necessary for its success. I have found that in some cases the number of organisms in the clear liquid is greatly increased, this being doubtless due to a reascension and multiplication of those which were at first carried down. Thus, in one series of experiments I obtained the following results:—

Untreated water	3000 organisms per cc.
After agitation with coke and	
26 hours' subsidence	20,000     "     "

Further experiments of a similar nature were made, but less time (only five hours) were allowed for subsidence:—

Untreated water	655 organisms per cc.
After agitation with coke and	
5 hours' subsidence	28     "     "
Reduction	= 96 per cent.

Thus, although a most remarkable purification may be accomplished by this simple process of agitation with the various substances specified, yet owing to the uncertainty of its success its efficiency cannot at present be relied upon.

Water was also agitated with several other substances such as china clay, brickdust, plaster of

Paris, oxide of manganese, etc.; all of these, however, yielded unsatisfactory results.

The removal of micro-organisms through the surface-attraction of suspended particles naturally leads us to a consideration of what takes place when the suspended particles are generated in the water itself by way of precipitation.

### III.—PURIFICATION OF WATER BY PRECIPITATION.

As by far the commonest and most important method of water purification dependent upon precipitation is the well-known Clark's Process, the effect of this on organised matters was made the subject of special study. With this view I have examined the process both in the laboratory as well as on the large scale, as practised by manufacturers and water companies.

#### LABORATORY EXPERIMENTS.

For testing the efficiency of the process on the laboratory scale, three stoppered Winchester quart bottles were taken, and to each were added two litres of ordinary London (Thames) water, to which a convenient proportion of organisms had been imparted by the addition of urine-water. To two of these bottles 100cc. of clear lime water were added, this being calculated to remove 116 parts of carbonate of lime per 100,000 parts of the water. Each of these bottles was violently shaken, and then allowed to subside for eighteen hours. The third bottle, to which no lime water had been added, was first tested for the number of organisms contained in the experimental water. After eighteen hours the two bottles to which lime water had been added were tested without disturbing the precipitate, as was also the third bottle, which had been left at rest in the same place as the other two. These tests showed the following numbers of organisms to be present in the water before and after treatment:—

Untreated water .....	83 organisms per cc.
" after 18 hours' rest .....	1922   "   "
Water after Clark's Process and	
18 hours' subsidence .....	42   "   "
Reduction on original = 51 per cent.	

In order to appreciate the real value of the treatment by Clark's process, it is necessary that the treated waters should be compared not only with the original water, but also with the untreated water after eighteen hours' rest, for the latter obviously indicates what the condition of the water would have been at the time of examination if no lime water had been added. It appeared to me probable that, after the subsidence of the carbonate of lime precipitate had taken place, the organisms which had been carried down by the latter would again become distributed throughout the upper layers of the water, and in order to ascertain whether this was the case or not, the same waters which had remained stoppered up and at rest were again examined after the lapse of ten days. It was then found that the untreated, as well as the softened waters, contained immense numbers of organisms in their upper layers.

In another series of experiments carried out under the same conditions, excepting that twenty-one instead of eighteen hours were allowed for the subsidence of the carbonate of lime, I obtained a reduction in the number of organisms amounting to forty-one per cent.

#### EXPERIMENTS ON INDUSTRIAL SCALE.

It appeared to me to be of great interest to ascertain what results can be obtained by Clark's process on the large scale. For this purpose the process of softening, as practised at the Colne Valley Water-

works at Bushey, near Watford, was investigated, as well as the new modification of Clark's process devised by Messrs. Gaillet and Huet, which is now in operation at Mr. Duncan's Sugar Refinery, Clyde Wharf, Victoria Dock. I am indebted to Mr. Verini, of the Colne Valley Waterworks, as well as to Mr. Duncan and Mr. Newlands, for their kindness in permitting me to carry out these experiments.

At the Colne Valley Waterworks, the hard water, obtained from a deep well sunk into the chalk, is mixed with the requisite proportion of clear lime water, and then allowed to settle in open tanks. The subsidence is so rapid that under favourable circumstances the upper layers of water are, after three hours' time, fit for distribution. On the occasion of my visit, however, boring operations were being carried on, and the water was, in consequence, milky, and the necessary subsidence after softening had to be increased to two days. I was unfortunately unable to obtain a perfectly representative sample of the water before softening, and the number of organisms found in the untreated water is probably in excess of that which was present in the unsoftened water actually employed. The following results were obtained:—

Unsoftened water .....	322 organisms per cc.
Water after softening and 2 days'	
subsidence (from main) .....	1   "   "
Reduction = 99 per cent.	

In Gaillet and Huet's process, as carried out at Mr. Duncan's, the water from an artesian well sunk into the chalk below the London clay, is mixed with a suitable proportion of lime water and caustic soda, the mixture being then made to pass upwards through a tower provided with oblique diaphragms, which accelerate the precipitation of the carbonate of lime. The passage through this tower occupies a period of about two hours. Samples of the water, before and after treatment, were examined with the following results:—

Well water from tanks .....	182 organisms per cc.
Softened water .....	1   "   "
Reduction = 98 per cent.	

These results, and especially those obtained on the industrial scale, conclusively prove that Clark's process is a most valuable agent for purifying water biologically, and the value of the process, from a chemical point of view, is illustrated by the following analyses:—

	Total Solids.	Parts per 100,000.	Org. C.	Org. N.	Hardness.
Caterham Water Supply .....	27.68	.028	.009		21.2
before softening .....					
Ditto after softening by .....	8.80	.015	.003		4.4
Clark's Process .....					

#### GAILLET AND HUET'S PROCESS.

	Well at Clyde Wharf, Victoria Dock.	Ditto after softening.
Total Solids .....	88.76	11.20
Organic Carbon .....	.111	.081
Nitrogen .....	.017	.016
Ammonia .....	.050	.060

#### Suspended Matter. —

Mineral .....	.22	—
Organic .....	.10	turbid.
Total .....	.32	—

On comparing the reduction of the organic matter, as indicated by chemical analysis, with the diminution

in the number of micro-organisms revealed by the biological examination, it will be seen that the biological efficiency of Clark's process is markedly superior to its power as a chemical purifier. This is obviously a matter of great importance, as it shows the value of methods of precipitation in removing micro-organisms; it must, however, be borne in mind that the particular precipitation-process which I have studied, is carried out with the greatest care and cleanliness, and it would obviously be highly out of place to compare with this many of the slovenly and farcical performances which enjoy the title of "Sewage Precipitation." It is a rule to which there is no exception, that satisfactory results, as regards the removal of micro-organisms, can only be obtained when the most scrupulous care and continuous attention are given to the matter, and failure will inevitably result when such processes are entrusted to ignorant and inexperienced persons.

#### IV.—PURIFICATION BY NATURAL AGENCIES.

It is a matter of common knowledge that of natural waters the purest, as regards organic matter, are those which have undergone prolonged filtration through porous strata. Such waters obtained from deep wells and deep-seated springs often contain the merest trace of organic matter, which is only discoverable and capable of being quantitatively determined by the most refined analytical methods. It has also been shown by Pasteur that many of these waters are entirely destitute of organic life, or in other words *sterile*. Of a number of waters of this kind, I have only met with one sample that was absolutely free from organic life, although some have closely approached this ideal state of things. It must, however, be remembered that the collection of natural waters of this kind, in a sterile condition, is fraught with great difficulty, inasmuch as the places where such waters issue are almost invariably surrounded by conditions which favour the communication of organised matters to the water. Thus the damp earthy surfaces, with which the issuing water comes in contact, form a favourable seat for the development of many growths. This difficulty is nowhere more apparent than at the Deptford well of the Kent Co., from the mouth of which several millions of gallons of water are daily disgorged. No more suitable place could, at first sight, be imagined; but a closer inspection shows that the pump rods and other surfaces with which the water is brought in contact, are coated with green vegetable life, and my monthly examinations of this water show that each cubic centimetre contains its complement, a small one only it is true, of organic life capable of growth and multiplication in the gelatine peptone medium. Thus the water collected direct from the Kent Co.'s well at Deptford contained:—

June 4th, 1885.... (temp. 12 $\frac{1}{2}$ ° C.)	6 organisms per cc.
Oct. 20th, "..... ( " 12 $\frac{1}{2}$ ° )	5 " "
Nov. 23rd, "..... ( " 11 $\frac{7}{8}$ ° )	8 " "

Again, the water from a spring, the Upper Greensand, near Reigate, contained:—

June 5th, 1885 .....	8 organisms per cc.
----------------------	---------------------

In the application of the gelatine process to the examination of potable water, I wish to point out that our opinion as to the biological purity of the water should be based, not only upon the aggregate number of organisms found, but also upon the number of different varieties which the cultivation reveals. A water containing only one or two varieties is, *ceteris paribus*, to be preferred to one in which there are many varieties, as in the latter case it is evident that the water has been subject to numerous sources of contamination, and that it has not been exposed

to influences inimical to the life of a number of different classes of micro-organisms. In my experiments on the artificial purification of water, I have always found that it is more difficult to remove some classes of organisms than others. Thus, those which cause liquefaction of the gelatine appear to offer least difficulty in their removal. I could quote numerous instances of this, but the following case illustrates this point in a most striking manner. In the experiments on filtration through vegetable charcoal, we have already seen that the

Unfiltered water contained ...	2230 organisms per cc.
Filtered " " " " " "	506 " " " "
Reduction =	77 per cent. " "

If, however, we only take into consideration the organisms causing liquefaction of gelatine, we find

Unfiltered water contained ..	785 organisms (liq.) per cc.
Filtered " " " " " "	1 " " " "
Reduction =	99 $\frac{87}{100}$ per cent.

#### GELATINE PROCESS APPLIED TO LONDON WATERS.

For more than a year past I have made periodical examinations by this process of all the waters supplied to the Metropolis, and the first results which I obtained were made known in a lecture which I delivered in February last, at the Parker's Museum of Hygiene and subsequently at the Royal Society. At the request of Col. Sir Francis Bolton, I now furnish these results (see page 706) regularly to the Local Government Board, and they are published in his, the Official Water Examiner's monthly reports.

The results of these examinations are of peculiar interest when they are studied side by side with the results of similar examinations made of the river waters from which the Metropolitan supply is mainly derived. It is, of course, impossible to obtain perfectly representative samples of the water before and after treatment by the companies, but the plan which, after reflection, I have adopted, and which appears to me to be the only practicable one, is to collect samples of the river-water as it passes the companies' intakes on the same day as that on which the samples of the water actually supplied to the consumer are taken. In this manner the samples, taken over a considerable period of time, will be representative of the average quality of the river-water on the one hand, and of the actual supply on the other. A mere glance at the results of these observations, which are embodied in the annexed table, will distinctly show the striking improvement, as regards removal of organic life, which the river-waters undergo in passing through the companies' works. Taking the average of three such observations, it will be seen that the micro-organisms in the river Thames have been reduced to the extent of 86 per cent. before reaching the consumer.

It is obvious that by this method of examination a most valuable check can be kept upon the working of the filter-beds and other purifying plant of water-works.

It is necessary to add some words of explanation with regard to the difference in the number of organisms found in the water of the Kent well, and in that supplied to the district of the same company. The water of the Kent Company leaves the well, as is seen, almost wholly destitute of organic life, and the few organisms which it does contain are almost certainly imported into it in passing over the surfaces at the mouth of the well already referred to. These newly imported organisms are placed in a position particularly favourable for their growth and development, the plant-food which the water contains not having been exhausted by previous generations of micro-organisms. The consequence is that this small com-

plement of organisms undergoes considerable multiplication before reaching the point in the district where the other samples are collected.

In the case of the river-water, the conditions are entirely different. During the flow of the river from its source, down to the intakes of the companies, the water has received a continual accession of organisms from various sources, and these have had undisturbed opportunity of reproduction limited only by the temperature and the amount of food which they have found in the river; this water enters the storage reservoirs of the companies, where the food present in the water is more or less exhausted according to the length of the period of storage; the water then passes on to the filters, where by far the greater number of organisms are removed, and those which find their way through, or are accidentally introduced after filtration, find less opportunity of rapid multiplication in this more or less exhausted medium, than do the organisms imported into the virgin soil of the deep-well water. In time, however, these organisms in the filtered river-water also multiply largely, for I have found that if the water for chemical analysis contained in the ordinary sample bottles, which are used exclusively for the waters of the respective companies, be submitted to examination with gelatine, a very much larger number of organisms are invariably found. Thus: Grand Junction Co.'s water, in November, 1884, from ordinary sample-bottle which had been standing in the laboratory, contained upwards of 89,000 organisms in 1cc.

Number of organisms in the water was ascertained at the outset of the experiment, again at the end of 6 hours the number was determined in one of the bottles, at the end of 24 hours in the second bottle, and lastly, at the end of 48 hours, in the third bottle. The numbers found were as follows:—

Hours of Subsidence.	No. of Organisms in 1cc.
0 (morning) .....	1,073
6 (evening) .....	6,028
24 (morning) .....	7,262
48 (morning) .....	48,100

The comparatively small increase between the 6th and 24th hour is accounted for by the low temperature which must have prevailed during the night, the increase during the first 6 hours being during the daytime. In the last number of the *Chemical News*, I see that these results have been recently confirmed by Dr. T. Leone, in the case of a pure spring water at Munich, which reaches the town with five organisms in 1cc.; but on standing 24 hours, contains more than 100; in 2 days, 10,500; in three days, 67,000; in 4 days, 315,000; and on the fifth day, more than half-a-million in 1cc. The temperature at which this multiplication took place was 14–18° C.

The principal conclusions to be drawn from the experiments to which I have referred, are:—

1. That the complete removal of micro-organisms from water, by filtration, is unattainable without frequent renewal of the best filtering matters, and duly restricting the rate of filtration.

I have had, moreover, repeated experience in the laboratory of the fact, that if a water which is comparatively free from organisms be inoculated with a few drops of a fluid highly charged with organisms, the latter will multiply with astonishing rapidity. I have already pointed this out in the case of some of the experiments with agitation and Clark's process, detailed above, and it is still more strikingly illustrated by the following experiments, which were also published before the Royal Society. Many litres of ordinary distilled water were impregnated with a few drops of urine-water containing abundant organisms; this infected water was placed in three sterilised Winchester quart bottles, plugged with sterilised cotton-wool, and the bottles were placed in a room, the average temperature of which was about 10° C. during the daytime, and left at perfect rest. The num-

2. That a very great reduction in the amount of organised matter in water may be accomplished by filtering materials, which have hitherto been generally regarded as almost ineffectual.

3. That organised matter is, to a large and sometimes to a most remarkable extent, removable from water by agitation with suitable solids in a fine state of division, but that such methods of purification are unreliable.

4. The chemical precipitation is attended with a large reduction in the number of micro-organisms present in the water, in which the precipitate is made to form and allowed to subside.

5. That if subsidence, either after agitation or after precipitation, be continued too long, the organisms first carried down may again become redistributed throughout the water.

In introducing this method of investigation to the notice of the Society, I should point out that it is only by bestowing the most scrupulous care on every detail of the process, that reliable results can be obtained, and any carelessness must inevitably, sooner or later, be followed by failure. In connection with this I may appropriately quote the following words of Dr. Klein—"Micro-organisms and Disease": Macmillan & Co., 1885:—

"All this may appear to some rather tedious and unnecessarily complicated, but it cannot be too strongly insisted on that in these matters one cannot be too scrupulous. A slight relaxation may, and occasionally is, followed by disastrous consequences, in the shape of accidental contamination, and consequent loss of material prepared at the cost of much labour and time. Several weeks' work may be annihilated by a single omission. Sometimes one is perhaps in a slight hurry, and does not think the want of an additional heating of the test-tube or cotton-wool, or an additional boiling of the fluid, will be followed by any bad consequences. But, alas! Nature does not take into account our convenience, and failure is our reward. If in any experiments 'overdoing' is an error in the right direction, it is in these very experiments on the cultivation of micro-organisms."

In conclusion, I must express my thanks to my assistant, Mr. A. W. Bishop, for the invaluable aid which I have received from him, in conducting my later experiments.

#### DISCUSSION.

Mr. Bischof said he had taken a number of notes; but, as he expected to have the honour of reading, in February, a paper on a subject somewhat similar to that before the meeting, he would confine himself to such points as he did not then intend to deal with. The author of the paper mentioned that he had found it necessary, on account of the summer heat, to increase the quantity of gelatine. Now, this had never happened in his own experience. He had had the privilege of studying this method in Dr. Koch's private laboratory in Berlin, and had followed his method exactly. Of course, there might be improvements; and he himself looked forward with great pleasure to trying some of the modifications mentioned that evening. The mixing of eggs with gelatine was quite foreign to Dr. Koch's procedure. He (Mr. Bischof) understood the author to say that gelatine was filled into clean test-tubes. Did he mean by this sterilised tubes? Dr. Koch sterilised the test-tube before the gelatine was filled in, which he considered quite essential. He sterilised the gelatine in the test-tubes themselves by exposing them in the apparatus on three consecutive days to steam for fourteen minutes each day. The procedure of burning the cotton wool, described in the paper, was not practised by Dr. Koch. The wool stopper was simply taken out with the hand, the sample introduced, and the stopper at once replaced. It was again taken out when the sample had to be spread on the glass plate, and before pouring out the gelatine the mouth of the test-tube was passed through a Bunsen flame in order to destroy any organisms which might adhere to the outside. The temperature of 20° to 25° for incubation appeared somewhat high. He found his gelatine at 25° became very soft. With regard to the filtration experiment, he thought it would have been an improvement if Dr. P. Frankland had employed the materials of such size and grain as could be practically used; for he feared materials which had been passed through a sieve having forty meshes to the inch could not be employed practically. Filters so constructed would be too "choky;" and, therefore, the valuable deductions made could not with perfect certainty be

applied to practical working. Again, if these experiments were continued, he would ask the author to consider whether he could not carry them on with different materials simultaneously, supplying them all from a common reservoir; as, in that case, the results could be better compared. It was not sufficient to state that one water contained so many organisms, and another so many. They might differ in kind; and on this the result would greatly depend. He did not quite understand why the most natural unfiltered water had not been taken—viz., diluted sewage. Of course, urine would tell a great deal, for there was a considerable quantity of urine in sewage; but why not take dilute sewage itself? In his experiments, he had invariably used sewage filtered through paper to which 1 per cent. of river water was added. He could thoroughly confirm, from his own experience, the enormous increase which took place on standing in water, even of good biological quality.

Mr. SALAMON thought it was to be regretted Dr. P. Frankland had not made special cultures of the different organisms filtering through the various materials. Had he done so, he would have found that there was a certain selective preference exercised by these materials in regard to their sterilising powers. He had made some experiments in this special direction, having been consulted with reference to a "fret," or after-fermentation, which had been manifested in certain beers during the recent summer weather. After looking thoroughly into the matter, he came to the conclusion that the water was impure for brewing purposes. Of course, he need not say the small quantity of organic matter being normal in amount, did no harm whatever for this purpose. He found, on culture of the water, that he could ascertain and identify the presence of certain specific organisms. Happening to call at South Kensington, he mentioned the matter to Dr. P. Frankland, and had the advantage of discussing it with him and Dr. Frankland, senior, when they both advised him to filter the water through coke. Acting on this suggestion, he had some large filters fitted up, the coke being in a fine state of division, and passed the water through it; and he must say the results were most satisfactory. The fret disappeared; and though the beer was perhaps a little flattened, the result, on the whole, was good. In fact, the utmost satisfaction was given by the treatment adopted. He communicated these results to Dr. P. Frankland, and told him also that he had discovered certain facts with regard to the chemical action on these points, upon which he saw they were not agreed. He was afterwards consulted on another question of an exactly similar nature, where he found that the organisms which caused the trouble in question were not the same. He tried a coke filter again, with exactly the same rate of filtration, and arrived at the conclusion that in this case the coke filter was absolutely useless. It did not keep back the specific germs to the same extent as in the water first treated, so that it was useless as a steriliser. In both cases he used the same kind of coke. The author, in his experiment respecting the change in chemical composition, did not make any mention of the kind of coke; but this seemed most important. Coke varied very much in composition; and the chemical composition of the water passing through it was considerably affected by the composition of the coke itself. The sole experiment narrated of passing water through six inches of coke in a small tube was almost insufficient for testing chemical composition. He made many hundreds of experiments in this direction; and for this purpose took a tube 30 inches long and 3 or 4 inches in diameter, filled it with ground coke, and passed the

water through it, and he found that the effects produced on the water before and after were so pronounced as to be in all respects comparable to those obtained by filtration through spongy iron. If, however, he took the same coke, and boiled it with hydrochloric acid so as to remove certain mineral matters, he obtained negative results. This seemed to point to the existence of a couple between the iron and the coke which must necessarily vary with the composition of the coke itself; and, of course, it was possible to accentuate the action of the couple. On seeing the marvellous results obtained by these filtering materials, it was somewhat difficult to contend that it was possible for such an action to take place without some corresponding chemical action; and he believed, if Dr. P. Frankland would repeat the experiments, he would find that the chemical changes he had pointed out were in all cases correct. Another point was the chemical composition of the nutritive materials. This was stated to be neutral; but he thought if it were slightly alkaline it would be better for the growth of the organisms likely to occur in water.

Dr. MESSER thought these experiments seemed to show that, whatever filtering material was used, after a time it became inoperative, and indeed seemed to introduce foreign matter into the water. Speaking of Gaillet and Huet's modification of Clark's process, where there was a portion of the precipitate which, notwithstanding it was frequently blown off, remained in the apparatus, after a certain lapse of time this exercised a contaminating effect on the water itself. He should have thought that this, while being an excellent apparatus for the purification of water from one point of view, would be the very agent for introducing as many microbes into it as possible. Of course, where sulphate of lime is present in the water, and, through the addition of soda, sulphate of soda, this may be destructive to the lower organisms; but this does not hold good of the original Clark's process, where lime is used, and which gives water equally free from microbes.

Mr. B. E. R. NEWLANDS said in the Gaillet and Huet process, at Clyde Wharf, the use of the soda produced a gummy precipitate not to be found under the ordinary Clark's process, and he could quite understand that this would make a considerable difference in the number of micro-organisms, as they would be dragged down by the precipitate. In Clark's process, this precipitate was crystalline; but, in the other case, it was a gummy and tenacious sort of mass. With regard to what Dr. Messer had said, he might mention that the precipitate was drawn away two or three times every hour, so that there was little likelihood of any unfortunate micro-organisms having a chance to rise. Some of these micro-organisms on the screen appeared to be very much larger than others. Several were like vast continents, and others like small islands. The author pointed them out, and counted them up exactly as if they were all alike. He was not familiar with this class of work, but it appeared to him that these great colonies deserved more attention, and that it would be better to measure them, and to state that there were so many square inches in a certain amount of water instead of merely counting them.

Mr. CROWDER said it would appear that there is some relation between the water and the medium through which it passed; and he should like to know if Dr. P. Frankland had made any experiments as to the quantity of water which could be sent through a certain medium. For instance, he took coke or animal charcoal: but could he give the meeting any comparative table of the quantity of water which passed through coke until it became con-

taminated, and the same with spongy iron and charcoal?

Mr. CRESSWELL asked if Dr. P. Frankland could say what characters the water developed after being agitated with the various materials, and precipitated as mentioned in the third division of his subject. Were any differences observed as to their capacity for developing organisms?

Dr. P. FRANKLAND, in reply to Mr. Bischof, said that eggs were used by a number of bacteriologists; and although this was Dr. Koch's process, it was now the property of the scientific world, and anyone was at perfect liberty to introduce an improvement. There could be no doubt that the introduction of eggs greatly facilitated the clarification of the liquid, and many authorities, including Dr. Klein, recommended their use for this purpose. With regard to the sterilisation of the apparatus, the only point on which his procedure appeared to differ from that of Dr. Koch, was that the tubes were not sterilised before the gelatine was introduced, but they were thoroughly washed and cleaned with acid. What was the use of sterilising test-tubes into which a liquor was going to be poured which was not itself sterile? When the gelatin was filtered into them, it was not sterile at all, having been exposed for a whole day during filtration, and might contain many organisms; but as soon as it was in the test-tube it was exposed to the crucial process of sterilisation with steam for half-an-hour on three successive days. The lapse of this interval between each steaming was of the greatest importance. The burning of the cotton wool he took to be a very important point. The wool was exposed to all kinds of contamination from the atmosphere, and doubtless the surface was covered with many organisms; and it was burnt so as to get the surface completely sterile, and then gradually removed—the edge of the tube being heated in the flame in case anything should lodge there. On the whole, his process agreed extremely well with that of Dr. Koch, and, at any rate, was not open to any objection on the score of sterilisation, because he produced sterile plates when he operated with sterile water. Operating with a corrosive sublimate seal, it was obvious the process was very complete, otherwise he should not get these sterile plates. With regard to the degree of fineness of the filtering media, when he commenced these experiments he was so sceptical as to the filtering power of any medium, that he thought he would give these substances the best chance he could, and therefore used the very finest materials. He did not think it was absolutely impossible to use such materials on a large scale, for he had had some filters of considerable size constructed of coke of the fineness described. He believed it was somewhat troublesome to prepare this coke; still it was done. He entirely agreed with Mr. Bischof that it would be more satisfactory if all these filtering experiments could be carried on side by side, the supplies being drawn from a common reservoir wherever practicable; and the unfiltered water was one and the same. The same water also was used for the filtration and precipitation experiments whenever possible; and he had given all the filters the same raw materials to deal with. He quite agreed with Mr. Salamon, and had pointed out in the paper that there was undoubtedly a certain amount of selective action on the part of these various filtering substances; he had pointed out also that the liquefying organisms were apparently most easily removed. With regard to the chemical action of the coke, he would ask what the composition of Mr. Salamon's coke was, because his coke, instead of reducing nitrates like spongy iron, produced them. He understood Mr. Salamon to say that if it passed through thirty inches of coke the nitrates would be destroyed.

Mr. SALAMON said there was an increase in the ammonia.

Dr. P. FRANKLAND said the nitrogen must appear somehow, either as ammonia or as nitrates. In his experiment it appeared as nitrates, and he could not very well conceive how it was that by lengthening the filtering-tube, a different effect should be produced.

Mr. SALAMON said the organic carbon would be reduced from 0.14 to 0.05. He had had results in which the nitrates had gone to nothing; but, of course, the ammonia was correspondingly increased.

Dr. P. FRANKLAND said this must obviously be due to some difference between the cokes employed. It was quite reasonable to suppose that spongy iron should be formed in coke; there was a certain quantity of pyrites in the coal, which, at the high temperature of the gas-retort, would doubtless appear, to some extent, as spongy iron; but this did not seem to be the action of the coke of which he had made use. He did not think the waters could have undergone nitrification in the bottles, as the time was so short. With regard to the reaction of the nutritive medium, which he had described as neutral, one could only say that such an originally acid body was neutral when it was slightly alkaline. It would not do to exceed this alkalinity; and probably the neutral medium indicated the growth of the maximum number of organisms. The most satisfactory way of performing the test, although it would complicate it, would be to use three media; to put up one plate with an acid, another with a neutral, and a third with an alkaline medium. It was possible to go still further than this, and surround one with an atmosphere of air, another with an atmosphere of carbonic anhydride, and a third with an atmosphere of nitrogen. In fact, there was no limit to the degree of completeness to which this method might be carried. It must not be supposed that the number of organisms found absolutely represented the number contained in the water. There might be organisms which did not thrive in this particular medium. It was well known to bacteriologists that there were organisms which did not thrive well until a much higher temperature was obtained than could be used with this gelatine medium. Mr. Bischof said his gelatine became very soft at 25° C.; but some pathogenic organisms required a temperature of upwards of 30° to develop with any vigour. This brought him to the point mentioned by Mr. Newlands—that to gauge the activity of the organisms one should measure the size of the colonies to which they gave rise. Of course, this difference in the size of the colonies was mainly dependent on the fitness of the medium for their growth. These enormous liquefying colonies were doubtless those which flourished best, in this particular medium; but he did not think it would be a fair mode of proceeding to consider the size of a colony produced as any measure of the importance of the organism present. Of course, as bacteriology progressed, the properties of the organisms belonging to each colony would be more definitely known. With regard to the remark of Dr. Messel about the precipitated carbonate of lime in Gaillot and Hue's process acting as a source for importing organisms into water, as Mr. Newlands had pointed out, this carbonate of lime was drawn off two or three times an hour from the diaphragms; and, therefore, any accumulation of material tending to foster organisms was prevented. He had pointed out that, if the water were allowed to stand in contact with the precipitated carbonate of lime, a re-ascension of the organisms took place; and the water became just as fully charged with them as it was before the softening process. Mr. Cresswell's remarks undoubtedly

indicated an interesting field of investigation—viz., a study of the relative rate in which organisms multiply in various waters. It would be interesting to try whether the organisms would multiply more rapidly in the Kent chalk waters than in the river waters, which his experience showed apparently they did. He had only examined this in a few cases; but it was obvious that it might be extended.

The CHAIRMAN said chemists had long felt that it was very difficult for them to venture on an opinion as to the value of a potable water in many cases, and they had been anxiously looking out for the introduction of some such method as that before the meeting. It must be a source of congratulation to the members that Koch's method was being taken up in this country by one who fortunately possessed the qualifications of the chemist, because it was useless for a matter of this sort to be dealt with simply by a biologist, who would look at it from a too one-sided point of view. It was essential that someone who would take pains to carry out the biological method with the necessary care, and who at the same time possessed the requisite chemical knowledge, should attack the question. The criticisms passed on the paper tended, for the most part, to show that Dr. Frankland had materially improved the method, for Mr. Bischof's complaints were rather directed against the excessive precautions taken.

## NOTE ON THE DECOMPOSITION OF AMMONIUM CHLORIDE SOLUTION BY CALCIUM CARBONATE.

BY FRANK L. TEED, D.S.C.

THE late Dr. James Young patented in 1872 (No. 2988) the decomposition by calcium or magnesium carbonates of the ammonium chloride solution produced in the ammonia soda process. His process is to boil the solution with about  $\frac{1}{2}$  equivalents of the carbonates of lime or magnesia in a still or boiler; but he could not succeed in making the decomposition complete, so that at the end he was obliged to add about one-third of an equivalent of lime, to get off his residual ammonia. I am not aware that this process was ever worked, and I believe it is now of purely historical interest.

I found with regard to the mutual action of calcium carbonate and ammonium chloride that the decomposition was complete on prolonged boiling in a dilute solution. By taking a very strong solution, however, I did not succeed in producing complete decomposition, although I carried on the boiling with occasional replacement of evaporated water for about two days; it is but fair to add that traces of ammonia were still being evolved.

It would appear from this that in Young's process the chance of the ammonia being evolved became less and less the more he boiled off his water.

I found, by allowing a solution of ammonium chloride to slowly trickle down a tower filled with small pieces of marble, up which steam was being blown, that it was possible to get the runnings from the tower free from ammonia and to obtain solid carbonate of ammonia at the top according to the equation—

The tower I used was 5 ft. 4 in. in height, and nearly 2 in. in internal diameter.

To quote two experiments:—

Amount of $\text{NH}_4\text{Cl}$ taken.	Dissolved in water to	Runnings made to	Percentage of total $\text{NH}_3$ in runnings.
5.35 grammes	100cc.	1000cc.	0.16
13.375 grammes	50cc.	1000cc.	less than 0.1

The ammonia in the runnings was estimated by Nessler's solution. Although I started with fairly strong solutions, in the second case about saturated, the steam condensed in the tower diluted the runnings to a huge extent. So that although it is plain that a dilute solution of ammonium chloride is decomposed completely by calcium carbonate, and a strong one is not, or only very slowly, it still remains to determine the precise limit of strength of the solution decomposable by calcium carbonate.

This reaction, worked on the large scale, would, in the ammonia soda process, save the production and pumping in of carbonic acid, for instead of decomposing limestone in kilns to obtain lime and carbonic acid, both of which are used subsequently,—the former for recovering the ammonia from the ammonium chloride liquors, and the latter for pumping into the brine with the ammonia,—the limestone would be at once decomposed by the ammonium chloride liquors yielding both ammonia and carbonic acid simultaneously.

As to whether this process would pay on the large scale is, I think, a question that can only be decided on the large scale.

It may probably be taken for granted that it would scarcely pay to dilute the liquors to such an extent as to drive all the ammonia off by means of limestone, but it would, I believe, be an advantage to use limestone as an accessory to the lime now used.

It is customary, I understand, before treating the ammonium chloride liquors with lime, to allow them to trickle down a tower filled with some inert substance up which steam is being blown, in order to remove all carbonate of ammonia, existing as such in the solution. My suggestion is that this preliminary treatment should be conducted in a tower filled with limestone, marble, dolomite, magnesite, or other convenient form of carbonate of lime or magnesia, when not only the carbonate of ammonia existing as such in the liquors would be recovered, but a considerable proportion of the ammonium chloride would be converted into ammonium carbonate—I should anticipate to the extent of about two-thirds. This would save two-thirds of the limestone burning and two-thirds of the carbonic acid pumping, and would, moreover, be a neater arrangement.

MEETINGS, SESSION 1885—86.—First Tuesday in each Month, at 7 P.M.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

## INDIARUBBER AND ITS DECAY.

BY WILLIAM THOMSON, F.R.S.E.

COMPARATIVELY little accurate information has been published respecting indiarubber, considering its commercial importance and the scientific interest it possesses.

Pure rubber is a white substance having a specific gravity somewhere about 915, and the purest commercial Para indiarubber has also a white, milky appearance, but on exposure to the air the surface gradually darkens in colour until it has become nearly black. It is soluble in the cold in carbon disulphide, and it is said to be still more soluble in carbon disulphide to which 5 per cent. of absolute alcohol has been added. It is also soluble in chloroform, naphtha, turpentine, and benzene.

Indiarubber at the ordinary temperatures of the air is soft and elastic, but if cooled down to the temperature of melting ice it becomes hard. If a piece of indiarubber be left stretched at the ordinary temperatures of the air, by means of a weight it will contract and draw up the weight if the temperature be increased to, say, 100° F., as shown by Dr. Joule and Sir W. Thomson. When heated to about the boiling point of water, it becomes soft and loses its elasticity. About 300° F. it begins to become still softer and to decompose, and about 400° F. it melts into a viscid liquid which never again becomes solid. This liquefied indiarubber is said to have the same percentage composition as pure indiarubber, which, according to Faraday, contains 87.5 per cent. of carbon and 12.5 per cent. of hydrogen, which gives nearly the empirical formula of turpentine ( $\text{C}_{11}\text{H}_{16}$ ). Indiarubber may be regarded as one of the terpenes, being evidently some polymeric modification of the radical above mentioned.

To counteract the objectionable properties of ordinary indiarubber, of losing its elasticity when subjected to considerable degrees of cold or of heat, a process called vulcanisation was introduced by Hancock about 40 years ago, which consists in chemically combining the rubber with a small percentage of sulphur. This is done by a number of different processes. If the rubber be immersed in liquid sulphur, according to Mr. T. Bolas, it absorbs as much as 50 per cent. of its weight of that material. This absorption of sulphur, however, does not bring about vulcanisation, because it has only been taken up by the rubber as a sponge would absorb water. If, however, sulphur be introduced into the rubber by this method, or by mechanical means, as is actually done in the manufacture, by intimately mixing the rubber with sulphur, by passing the mixture repeatedly between rollers, after the rubber has been brought into the consistency of putty by mastication,

or after it has been made soft and putty-like, by previously mixing the masticated or ordinary washed rubber with naphtha, the chemical combination of the sulphur and rubber may then be brought about by subjecting the mixture to a temperature of at least 275° F. Part of the sulphur, about 2 or 3 per cent., combines chemically with the rubber and completely changes its properties, producing vulcanised indiarubber.

The molecules of sulphur in excess in indiarubber move about to some extent after vulcanisation, and if too great an excess of sulphur is contained in the rubber employed for waterproofing certain kinds of cloth, which are covered by a mixture of rubber and sulphur and vulcanised by heat, where a smooth black surface is required, the excess, if too large, finds its way to the surface and forms a white bloom on the face of the rubber, which is considerably damaged thereby. After vulcanisation the rubber becomes more elastic than the raw material, and it retains that elasticity when cooled to the temperature of ice, or when heated to the temperature of boiling water. Thin layers of indiarubber may also be vulcanised by applying to it a mixture of sulphur chloride dissolved in carbon disulphide, according to the patent process of Parke, which is employed for vulcanising of the thin layers of Macintosh when heat would be liable to injure the cloth or the colours.

According to Professor William Allen Miller's extracts from the report of a joint committee appointed by the Lords of the Committee of Privy Council of Trade, and by the Atlantic Cable Company about the year 1860, to inquire into the construction of submarine cables, \* pure virgin indiarubber is less liable to undergo decomposition than masticated rubber, and I have been informed by Mr. Joseph Mosley, one of the firm of large indiarubber manufacturers of Manchester, that from his experience good Para virgin indiarubber will remain in good condition for any length of time, provided it be kept at the ordinary temperatures of the atmosphere and not exposed to the direct sunlight. The more it is worked or masticated, or if it be over-vulcanised, the greater liability is there afterwards of its decaying. Over-vulcanised rubber thread may be detected by attaching a given weight to any given length of thread of a certain count. The weight ought to stretch the rubber, if properly vulcanised, to a certain length; if however the rubber be over-vulcanised the thread will not stretch to the required length, and if it be under-vulcanised it will stretch farther than the required length. Indiarubber goes on combining with sulphur if the vulcanising process be continued till the caoutchouc is converted into ebonite. Well-vulcanised caoutchouc, after the excess of sulphur has been removed by boiling with caustic soda, is found to contain from 2 to 5 per cent of sulphur; but there is no basis for any theoretical quantity of sulphur being required. The decay of indiarubber was attributed by the joint committee in their report to the direct oxidation of the material of the rubber, and this oxidation Dr. Miller considered was most rapidly and completely brought about by the action of the sun's rays, when the rubber was exposed to the air.

When pure indiarubber was exposed by him to the action of the sun and rain in the open air during nine months, it gradually became blackened and rotten, but it neither became sticky nor hard. It had, however, increased in weight to the extent of 7 per cent. In rubber, however, which he exposed to direct sunlight and air, but which was kept dry in a bottle placed mouth downwards, the oxidation was less rapid, the weight having increased by 2·8 per cent.

It had become brown, soft and sticky, especially at the parts most exposed to the light. He found that rubber which had been masticated, was still more acted upon by the light and air, so that during nine months it had been converted into a sticky mass, which had lost its tenacity and elasticity, whereas pieces of vulcanised rubber were, according to his experiments, less acted upon by the sun and air during the nine months than either the virgin or the masticated rubber.

If a thin film of virgin indiarubber be exposed to the direct sunlight for a few minutes, the oxidation or decomposition which goes on, may be observed by its becoming sticky, but I have never observed this stickiness to be produced by the decay of vulcanised indiarubber, unless after it had come in contact with some kind of oil.

I have always observed that vulcanised rubber in decaying first becomes more easily broken when stretched, although retaining its original softness, and then it gradually becomes hard and brittle from the outside inwards. I have also observed that this oxidation is brought about very rapidly by leaving rubber exposed to the air at a temperature near to that of boiling water. It then rapidly increases in weight to the extent of from 4 to 8 per cent., and becomes almost as hard as, but more brittle than, ordinary vulcanite, which is produced on the large scale by heating the rubber to a temperature of about 280° F., with about half its weight of sulphur. It is possible that keeping indiarubber at the temperature of boiling water for some time, brings about not only oxidation, but also an increased amount of vulcanisation, because the rubber so treated becomes harder than any samples with which I have met which had undergone change by exposure to direct sunlight and air, or that which had gradually hardened out of contact with the direct rays of the sun.

It is stated by several authorities, that indiarubber is of a cellular structure; and it is doubtless the case, as may be seen by the microscope, that indiarubber, which has been partially dissolved in naphtha, and formed in sheets for the manufacture of rubber thread, is full of minute air spaces or bubbles. These spaces can most easily be observed after the rubber has undergone oxidation, which takes place to a greater extent around the walls of each air-cell than in the solid parts of the rubber between such cells. I found, by experiment, that the oxidised or partially decayed rubber acts as a mordant to aniline colours, so that if a fine section of the rubber be steeped in an alcoholic solution of an aniline colour and subsequently washed with alcohol, the walls of most of the air-cells remain more coloured than the other portions of the rubber, and they can then be easily observed. It is probable that the air thus contained within the rubber combines chemically with it, and brings about its decomposition when placed under conditions favourable to such change, because I have ascertained that if rubber be kept immersed in boiling water for several days continuously, it gradually becomes rotten, although it is difficult to understand how any oxygen could come in contact with it from the air, under those conditions, and I think we have yet to learn that caoutchouc is capable of decomposing water. Air is evidently mixed with the rubber during the process of mastication. I have observed that rubber, before mastication, had a higher specific gravity than that after mastication. The masticating process consists in putting the rubber, which has been previously cut into slips and washed between rollers, and dried, into a strong iron box, in which is working a hollow toothed or grooved roller, revolving with a slightly eccentric motion. The washed rubber is kneaded in this apparatus between the roller and the

walls of the box for 4, 5 or 6 hours, during which time it becomes sometimes as hot, or hotter than boiling water. Sometimes it is necessary to keep down the temperature by passing water through the hollow cylinder. It is evident that this heat in presence of air or oxygen would also produce oxidation, and bring about direct deterioration in the rubber, and it is possible that such oxidation may be essential to the process; but it would doubtless be a great improvement to the quality of the manufactured rubber if such oxidation could be prevented. One would think from the fact that the decomposition of rubber goes on more readily round the walls of the air cells, that it might be possible to make masticated rubber as little liable to decay as virgin rubber, by the comparatively simple expedient of preventing the formation of air cells and of oxidation by conducting the masticating process in vacuum, which might be done by laying the heavy doors of the apparatus against strips of vulcanised sheet india-rubber, and attaching the tube of an air-pump to one end of the box for the purpose of extracting the air.

Messrs. James Walton & Sons, of Haughton Dale, near Manchester, the manufacturers of cards for carding cotton, require to make a fabric for holding the steel wire teeth of the card by cementing a layer of sheet india-rubber on to a layer or layers of textile fabric. To produce sheets of rubber which will have a longer life-time than masticated rubber, they simply put the washed raw rubber, after being dried, into a cylinder heated to the temperature of boiling water, and force up a piston by hydraulic power to press the whole together into a solid mass. This cylinder of rubber is then frozen hard, placed in a machine adjusted so that knives cut from it a continuous sheet like the unwinding of a roll. This kind of sheet may be distinguished from the masticated sheet by the former being patchy in colour, though perfectly homogeneous in consistence, whilst the latter is homogeneous in both colour and consistency.

whole of the warp threads into series of knuckles or loops, which stood out from either side of the rubber threads. In some pieces of the web in question, a number of rubber threads became decayed, whilst a number of others remained sound, and it was alleged that the decaying of the damaged rubber threads had been brought about by something injurious to indiarubber which was contained in some of the polished threads which lay on one of the four faces of the rubber thread, and which was absent from the other polished threads which had done no damage. In this case the staining of the rubber threads with aniline colour, and the subsequent washing with alcohol, and microscopical examination threw a good deal of light on the cause of the decay.

To determine this, I cut a piece about 1 inch in length across the web (which was about 6 inches wide), put it into boiling water until all air bubbles had been thoroughly removed from the thread. It was then placed in a solution of previously purified transparent fish glue, then tightly coiled into the form of a cylinder 1 inch long by  $\frac{3}{4}$  inch diameter. This cylinder was then pushed into a cork with a large excess of glue still adhering to it, and allowed to dry. When dry the cork was introduced into a common microtome, into which it had previously been fitted, and fine transverse sections cut from it, which were then stained and washed with alcohol. The rim of cork was then removed from the section, which showed all the rubber and cotton threads *in situ*. The section was then mounted in glycerine jelly for microscopical examination. The following sketch shows part of the section of web, with all the indiarubber and cotton threads *in situ*.

The indiarubber thread in question had been prepared by the usual process of building up the sheet with a series of very fine layers of a mixture of indiarubber, sulphur and naphtha, which was subsequently vulcanised after the naphtha had evaporated; and it is remarkable, on looking at some of the threads shown in the sketch (which was drawn by the camera

The six light-coloured threads represent sound rubber threads; the shading round the edges and across the other three threads were crimson-coloured in the original drawing.

Some years ago, I was requested to find the cause of the decay of rubber threads contained in pieces of elastic web. Elastic web is manufactured by stretching the rubber threads as far as the web would be required to stretch, and then weaving it with warp and weft cotton or silk yarns. In the case in question, cotton yarns were employed, which had been purchased from different manufacturers. The web was black on the face and white on the back. The face was formed with black threads which had been polished with paraffin wax. Four of these threads lay lengthwise upon one face of each thread of rubber, and four corresponding white threads lay along the opposite face. Two binder warp threads were woven lengthwise between each rubber thread, and the whole of these threads being fixed by weft threads which went continuously round them.

After the web had been woven with the stretched elastic, it was allowed to contract, thus throwing the

whole of the warp threads into series of knuckles or loops, which stood out from either side of the rubber threads. In some pieces of the web in question, a number of rubber threads became decayed, whilst a number of others remained sound, and it was alleged that the decaying of the damaged rubber threads had been brought about by something injurious to indiarubber which was contained in some of the polished threads which lay on one of the four faces of the rubber thread, and which was absent from the other polished threads which had done no damage. In this case the staining of the rubber threads with aniline colour, and the subsequent washing with alcohol, and microscopical examination threw a good deal of light on the cause of the decay.

To determine this, I cut a piece about 1 inch in length across the web (which was about 6 inches wide), put it into boiling water until all air bubbles had been thoroughly removed from the thread. It was then placed in a solution of previously purified transparent fish glue, then tightly coiled into the form of a cylinder 1 inch long by  $\frac{3}{4}$  inch diameter. This cylinder was then pushed into a cork with a large excess of glue still adhering to it, and allowed to dry. When dry the cork was introduced into a common microtome, into which it had previously been fitted, and fine transverse sections cut from it, which were then stained and washed with alcohol. The rim of cork was then removed from the section, which showed all the rubber and cotton threads *in situ*. The section was then mounted in glycerine jelly for microscopical examination. The following sketch shows part of the section of web, with all the indiarubber and cotton threads *in situ*.

with them, so that when the rubber decays and loses its elasticity, the hardened rubber threads, on being removed, retain the impression of these knuckles.

The fact which gave a *prima facie* belief in the polished thread having caused the damage, was that the web manufacturer found several long lengths of web with two or three yards at the end, in which the rubber had decayed and lost its elasticity; and curiously enough, the rubber had commenced to decay at a line of knots across the web, where the polished warp having come to an end, had been joined up to fresh warp threads, all the other warps being continuous over this junction. This web was called "Terry" web; but there was also another "plain" web found by the manufacturer, in which there were no loops of thread covering the face and back; the only threads on that web were the binder warp, lying between each rubber thread, and the polished thread covering both back and front of the rubber threads, as weft. On examining the line at which the good rubber had been joined to the bad across this web, it was observed that exactly the opposite effect was shown, from what one would have expected, had the polished threads caused the damage. The manufacturer observed that a junction of the polished weft thread in this plain web, had taken place in the vicinity of the line across the web at which the rubber threads were damaged. In the "Terry" web, where the rubber was touched only on one face by the knuckles of the polished threads, it was damaged with a sharpness which might be compared to a knife cut; whereas the good rubber in the "plain" web ended in the form of a long wedge, although it was touched upon all four faces by the polished threads. The cause of this peculiar destruction of the rubber was no doubt due to the rubber having been left on the stretch in the looms in an uncovered condition for some time after the polished warp threads had become exhausted. The "Terry" web being better covered at the point at which the weaving was going on, produced a sharper line of damage than that in the plain web, in which the good rubber ended in the form of a long wedge. Rubber thread, when exposed during weaving to the light and heat in an uncovered and stretched condition in the looms, is very liable to undergo decay afterwards, as was shown by an experiment made by Mr. Friswell, of Coventry, who, after exposing the rubber thread in a stretched condition for some time in the loom, had them woven into web, marked, and put aside for some months; and although the rubber appeared reasonably good immediately after being woven, it had, after a few months, become greatly deteriorated, so that after being stretched out to its full extent, the injured parts did not contract like the uninjured, but formed what the manufacturer called a "baggy" appearance. The selvages being composed of two rubber threads, put together, each of which was thicker than those put in the body of the web, these not having undergone oxidation to the same extent as those in the body of the web, contracted to the full extent, the "baggy" appearance between the two selvages being caused by the greater oxidation of the interior threads, which was probably due (1st) to their being thinner, and therefore more easily oxidised, and (2nd) to their having been cut from different sheets of indiarubber, which might have been of better quality; and this "baggy" appearance in the experiment was precisely similar in nature to the damaged "junction webs" in question, because in them the selvege threads also remained perfectly sound.

I think it well to put the facts connected with this case on record, as it may be of interest to manufacturers of such webs; and although the verdict of the arbitrator was to the effect that the polished thread in question had caused the damage to the

rubber, yet it is quite clear that in his decision he was mistaken, as might easily have been shown if the arbitrator's reasons for coming to that decision could have been subjected to criticism before a higher court.

I have now had for about six years stretched indiarubber threads in contact with a sample of one lot of polished yarn, which it was alleged had actually caused damage to the indiarubber threads; these I examined a few days ago, and found them to be still quite sound. I chose to stretch the rubber threads in contact with polished cotton warp, because rubber threads which are stretched or pinched or strained in any way, are more easily oxidised at the parts subjected to such strain, than threads in their normal condition.

The sheets of indiarubber from which the threads are cut are white from the excess of sulphur which they contain; this excess is removed after the threads have been cut from the sheets, by placing them for some time in a boiling solution of caustic soda. I have observed in a number of samples of sheets of such rubber where one part of the threads had not had the excess of sulphur removed, whilst the other part was freed from sulphur by the caustic soda process, that the parts so freed from sulphur became quite rotten from oxidation, whilst that containing the excess of sulphur remained sound.

I think the most probable cause of this is that the particles of sulphur are removed. We know *they* do exist and that *they* are removed; and it is probable that when the water in which the rubber has been afterwards washed, evaporates, there remain the spaces which originally were filled with sulphur, and which afterwards became filled with air, the oxygen of which would aid in bringing about the decomposition. That the excess of sulphur occupied considerable space in the rubber threads after vulcanisation, is shown by the fact that one sample which I tested contracted 2½ per cent. on boiling in caustic soda. Completely oxidised indiarubber consists of hard resins, part of which is soluble in caustic alkalis, according to Spiller and to Professor Allen Miller. I have not specially examined this hard resin, but I have noticed that there is a soft amber-coloured viscid substance of the nature of indiarubber, which has been decomposed by heat and which increases in amount as oxidation proceeds. This substance is soluble in ether, and varies from 2 or 3 per cent. in the fresh vulcanised rubber, to 14 or 15 per cent. in that which has been hardened by oxidation; this soft substance is evidently produced simultaneously with the hard resins. I have kept some of it in thin layers exposed to the air for six years, and it now remains as soft as when it was first extracted.

When rubber is undergoing comparatively rapid oxidation or decay, it exhales a characteristic faintly pungent smell; and there is formed from it, besides the hard brittle resins and the soft amber-coloured greasy-looking substance above mentioned, a body volatile at the ordinary temperature of the air, to which the characteristic decomposing rubber smell is probably due, and which condenses on any material, such as white paper, in which the rubber may be wrapped, communicating to the paper an amber-coloured stain.

Vulcanised rubber appears to undergo decay or oxidation throughout before any hardening takes place, the material having, to the eye and to the touch, undergone no change whatever; the fact that it has undergone decomposition may, however, be easily demonstrated by merely stretching the rubber, when it will be found to break easily, whereas it would be quite impossible to break the fresh undecomposed rubber by the hands. According to the researches of Professors Graham Bell and Tyndall, indiarubber which has been highly

vulcanised is transparent to a considerable percentage of some of the solar rays, so that a piece of such rubber interposed between the rays and the selenium plate of the photophone does not prevent some of the rays from finding their way through the rubber, and continuing to alter the electrical resistance of the selenium at the other side. Tyndall says they are heat rays which pass through; still it is easy to understand that they, or the actinic rays, may expend their energy in the interior of the rubber in bringing about a chemical combination of the oxygen in the air-spaces with the rubber in their immediate vicinity; the excess of nitrogen from the air imprisoned in the cells would then soon dialyse out, fresh air with its fresh supply of oxygen taking its place.

Before leaving this part of the subject, it may be of interest to chemists generally to know that rubber corks, or other similar articles, which have become hard on the outside and therefore useless, may have their softness restored by the simple expedient of dissolving away the hard resin by leaving them for some time in a boiling solution of caustic soda.

With a view to find whether direct sun-light would have any action on rubber when placed in contact with gases other than oxygen or in a vacuum, I prepared two years and a half ago a series of experiments by enclosing four stretched rubber threads in each of the following gases: Hydrogen, carbon dioxide, oxygen, air, and in vacuum. One series was made with dry gases, and another with wet gases (a little distilled water being left in each tube), and each experiment was made in duplicate, the whole of the tubes being exposed as long as possible to the direct sun-light each day for several months. In *dry oxygen* all the threads in one of the tubes broke after a few days' exposure to the sun's rays, whilst in the other tube only one thread broke. On examination, a few days ago, all the threads were hardened,—they had not become nearly so hard as those which had been heated at the temperature of boiling water for a few days, but they were quite inelastic; the stretched threads, on being broken away from the frame in which they were stretched, remained quite rigid.

The volumes of the gases in which the rubber threads were enclosed ranged between 240 and 270 grains measure, and the weight of the rubber taken in each experiment was  $1\frac{1}{2}$  grains. In the dry oxygen about 20 per cent. of gas remained in the tube, the rest having been absorbed by the rubber, and by the iron wire frame, which unfortunately was used in these experiments. The gases left were roughly examined in test tubes, so that I will not give the results more minutely than by saying first, that most of the remaining gas was oxygen, and second, that carbon dioxide was present in small or in very small quantity.

I was less fortunate in my experiments with oxygen in presence of water, because in both tubes all the oxygen had been absorbed—mainly, no doubt, by the wet iron wire frames, so that in one tube there was almost a perfect vacuum, and the rubber in it was apparently not acted upon at all, whilst in the other tube the rubber threads were only rendered brittle, so that they could be broken easily when stretched; they retained, however, all the softness of good rubber threads.

In dry air the rubbers were quite rotten, but as soft as good rubber; they curled up when broken as rubber threads always do when they oxidise in a stretched condition.

The threads in dry and wet carbon dioxide were quite sound, likewise those in dry hydrogen, and in one of the tubes containing wet hydrogen. In the other tube containing wet hydrogen the threads were rotten, but I will not be positive that it actually decayed in presence of hydrogen, in case there might

have been some mistake, which I have reason to believe possible, I intend this experiment shall be repeated.

The threads which had been kept in vacuum appeared to be as sound as when first introduced, if not tougher and stronger.

From the above experiments it is evident that for practical purposes, so long as rubber can be kept away from the action of air or oxygen, it may be submitted to the action of direct sun-light, and another series of experiments showed that it might similarly be submitted to the action of the heat of boiling water, in presence of hydrogen, carbon dioxide, or in vacuum, without undergoing decay.

It might here be well to consider the method adopted by the natives in collecting crude Para rubber, which commands the highest price in the market. For this purpose, the milky juice of the rubber tree which flows from the incisions made in the bark, is collected in vessels like pails; a fire is made under a large earthenware pot, into which the nuts of the tree *Attalea Excelsa* are thrown at intervals; there is thus liberated from the nuts a heavy white smoke. A wooden bat is covered with soft clay, then dipped into the juice from the tree, which is of the nature of milk, and dried over the white smoke.

I have examined this white smoke, by distilling some of the nuts and condensing the vapour, when I obtained a watery liquid containing acetic, and a liquid dark coloured matter of an oily appearance. The acetic acid would no doubt aid in the coagulation of the juice of the tree, whilst some of the heavier oily-looking liquid would also condense over each layer of the dried juice. This oily substance I have found by experiment to have no injurious influence on indiarubber. Some partially vulcanised sheet-rubber was covered with this liquid, but it did not make the rubber swell so as to rise in a blister where it had touched, as happens with all the oils with the exception of castor oil. It remained liquid on the surface for two or three weeks, and gradually dried up to a pliable very dark-coloured varnish, which exhaled the peculiar aromatic odour of Para rubber. It is evident that this material, condensing on each layer of rubber on the bat of the native, must tend to fill up any pores, and thus tend to prevent the access of air to the body of the material, and render it more durable. Other methods are employed, which consist in precipitating the rubber from the milky juice by means of water, of dilute sulphuric acid or of alum. Thus precipitated, caoutchouc separates as a clot, which is simply allowed to dry, but which does not furnish the first qualities of the material. It would be interesting to learn whether the juices of caoutchouc trees, found in other parts of the world, if treated in a manner similar to that employed for the preparation of raw Para rubber, would furnish caoutchouc less liable to decay, and consequently of greater value, as it is probable that this mode of collecting and drying the juice has much to do with the quality and preservation of Para rubber.

The action of oils on caoutchouc is far from being thoroughly understood, although every one knows that many of them have a highly injurious effect upon it. It was, and possibly is yet, held by one or two chemists that oils put in small quantities on indiarubber tends to soften it at first, and afterwards to make it become hard by bringing about rapid oxidation. Six or seven years ago I commenced several series of experiments, by putting a large number of different oils on good vulcanised rubber thread. On some, one face of the rubber thread alone was painted over with the oil; the amounts put on the rubber varied from 1 per cent. to 100 per cent., or 200 per cent. on the rubber taken. I have examined all these a few days ago. Those which received the

small quantities of the different oils are quite sound and elastic to-day. Some of those which received the large quantities of oils are easily broken, but still soft like the original rubber thread, whilst few have become of a soft putty nature, having lost their elasticity. The conclusions at which I have arrived are that when certain oils are put in large quantity on rubber they have a strong tendency to induce oxidation in the rubber, which, with the oil, becomes of the nature of jelly; and if the rubber is really of good quality it remains in its expanded condition, due to the mechanical influence of the oil which it has absorbed, remaining elastic but easily broken when stretched. If, however, rubber in this condition be exposed to direct sun-light, or to a temperature of say 120° to 200° F. for a few days or weeks, it soon oxidises and becomes of a soft jelly nature, or melts at the high temperature into a viscid liquid which ultimately hardens if kept at the temperature of boiling water; but in no instance have I found that any oil when applied to rubber thread tended to make the rubber become hard when left at the ordinary temperature of the air in England, although I have done all I could to bring about such a result. If treated with drying oils, they of course might harden in time, that being due simply to the drying of the oil. I have further observed, when rubber thread was treated with some of the more injurious oils, and left in a heap in an envelope, that the parts which were outside and came most in contact with the air and light were softer or were more of a jelly consistence than the parts better covered; and I have further noticed that a piece of rubber so jellified, which I had put into a test tube, remained equally soft and jelly-like during six years. This jellifying or liquefying of the rubber when in contact with oil is brought about by the action of the oxygen of the air on the rubber, which may be illustrated by the experiments I show. Some good rubber thread was left in cotton-seed oil for four days, and when taken out it was found to be much swelled, but still comparatively firm and elastic. Four pieces of the thread were cut off and placed in four tubes, which were filled respectively with air, oxygen, carbon dioxide and hydrogen, and then hermetically sealed. These were made in duplicate: one set was placed in an incubator at 90° F., whilst another set was put into a bath at 200° F. The pieces of rubber in air and in oxygen became quite liquid in both sets, in the first set after a few days, and in the second within a few hours; whilst those in hydrogen and in carbon dioxide retained their form unaltered, even after being heated for a week at 200° F. About the end of the year 1883, I placed equal lengths of vulcanised indiarubber threads (2 inches) into different oils contained in test tubes, and left them where they would be heated to a temperature of from 80° to 110° F. for several hours each day. Here they were left for ten months, and on being examined it was found that the pieces of rubber contained in sperm oil, tallow oil, English neatsfoot oil, and American neatsfoot oil, were completely dissolved; these oils, though remaining quite fluid, had become more or less viscid.

Cotton-seed, olive, cod-liver and pale seal oils, had all swelled the rubber so much that it was rather difficult to see that they had not been dissolved, but in none of the last-mentioned had solution really taken place. The threads were laid in a U form from the bottom of the test tubes, the ends of the thread projected a little above the surfaces of the oils, and it was curious to notice that the parts of the threads at the immediate surface in the last-mentioned list of oils were completely dissolved away, whilst the pieces under the surface had swelled out to about two or more times the thickness of the original threads, and were exceedingly soft and jelly-like, but had not dissolved.

The piece of rubber in castor oil had apparently not been acted upon, so that after ten months it was as good and elastic as when it was first immersed. But when examined a few days ago (after being immersed for upwards of two years), and kept, as before stated, at a high temperature for several hours each day, it was then quite elastic and soft, and apparently quite sound; but it was really not quite sound, because when stretched it would not bear as much strain without breaking as the original rubber thread. Linsseed oil stood next to castor oil in this series as having acted least on the rubber thread. No part of the thread appeared to have dissolved in the linsseed oil, although it had swelled up and become gelatinous.

Generally speaking, the oil which is most destructive to the elastic properties of indiarubber when saturated with the oils and exposed to warm air is palm-nut oil and palm oil, some varieties of which have much greater effect than others. Thinking that this might be due to the fact suggested to me by my friend Mr. Percy J. Winsor, that some palm oils contain a much larger quantity of free fatty acids than others, and that the difference might be due to the free fatty acids, I estimated the amounts of free fatty acids in each, and found that the percentages did not explain the difference in the action of the different oils. Bleached palm oil, which had greatest effect on the rubber, contained 37.2 per cent. of free fatty acids, calculated as palmitic acid. The Bonny palm oil, which had least action, contained 31.1 per cent., whilst a sample of palm oil, which stood between these two in its action on rubber, contained 65.8 per cent. of free fatty acids. Palm-nut oil, which had more injurious action on rubber than any of the samples of palm oil, contained 13 per cent. of free fatty acids. The oil which had least action on rubber was castor oil.

Some time ago I examined a case of damage which might be of interest to indiarubber manufacturers, or those otherwise interested in it. Waterproof cloth is sometimes made by taking two layers of tweed or woollen cloth, covering each with a thin layer of indiarubber, which is then slightly vulcanised by the cold process; the two rubber layers are then laid together and pressed between rollers, so that they adhere firmly. Waterproof cloth thus made was shipped abroad to a warm country, and on arrival there it was found that the two pieces of cloth of which the waterproof fabric was composed had separated from each other, the rubber having become quite soft and sticky, and having become absorbed into the substance of the woollen. It became a question what had caused this; the person who bought the cloth and sent it to be waterproofed alleged that the rubber manufacturer had put in bad rubber, whilst the latter believed that there was something in the cloth which had caused the damage. I requested to be supplied with two pieces of the original cloth, which had not been treated, but the same as that which had become damaged after treatment, and fortunately I obtained them from the rubber manufacturer. I divided each into two parts, and from one of each I extracted the oily matter present by means of ether—

The one Sample contained	..... 1.37 per cent. of oil
And the other	..... " " "

No difference could be observed between the pieces from which I had extracted the oil, and the others, which were in their original condition. I marked them by different letters of the alphabet, and sent them to the manufacturer, requesting him to cover each with rubber in the usual way, and then to fold each on itself, the indiarubber layer being inside; these would then produce four pieces of waterproofed material. These so treated I obtained from the manufacturer, and placed them in an incubator at a

temperature of about 110° F. for about eight hours each day for fourteen days. On looking at them after that time, I found that two of the pieces were perfectly sound, and that it was impossible to separate the two layers from each other; whilst the layers of the other two pieces could be separated from each other, the layers of the one with 1·37 per cent. of oil separated easily, whilst that with '84 per cent. of oil with some difficulty, the rubber which bound them together having become quite sticky in each. I then referred to the marks on the pieces, and found that the two from which I had extracted the oil were perfectly sound, whilst those which had not been so treated had become useless as waterproof material. It may be thus taken that the small percentages of oils given above left in cloth which has to be waterproofed, will in all probability rapidly determine the decay of the rubber, especially if shipped to warm climates; and it might be well for manufacturers to treat small pieces of such cloth, and expose them to the temperature of boiling water for a day or two before treating the larger pieces.

If cloth which is required to be covered with a layer of polished rubber contains much oil—say a little over 1 per cent.—it is liable to produce dirt spots and stains all over the face of the layer of rubber on polishing.

With a view to obtain further information respecting the action of oils and other liquids which are capable of acting on vulcanised indiarubber, I took two rubber threads; the one was of count 34 and the other count 32—in other words, thirty-four pieces of the one, or thirty-two pieces of the other thread, when laid closely together would measure one inch. Both threads had been vulcanised, but the 34 count thread still retained the excess of sulphur, whilst it had been removed from the 32 count by a boiling solution of caustic soda. Two inches of the first thread, and three inches of the second were weighed and put together into each test tube, which was then half-filled with oil or other liquid to be tested, which completely covered the threads. The whole series was then left in an incubator at a temperature of 84° F. for exactly twenty-four hours, the tubes containing volatile liquids being corked, and all were again accurately measured and weighed after being dried thoroughly with blotting paper, and returned to the tubes for three days more, and again accurately measured and weighed as before. The table on page 717 gives the results of these experiments, calculated on 100 parts. The first two columns give the measurements of the first and second threads respectively, after twenty-four hours and after four days, the results given for four days being placed in different style of figure from those after one day, so that they may be the more easily compared. The third and fourth columns give the *weights of oil* which 100 parts by weight of rubber absorbed, and the fifth and sixth columns give (by calculation) the amounts of the different oils which would be required to expand the rubber to double its original length, assuming that such could be done. As a matter of fact, none of the substances employed expanded the rubber to double its length; but this arrangement of calculation is convenient, as it shows by merely altering the decimal point the relative weights of the different oils required to make 100 parts by measure of the same rubber thread expand to 101 or to 110 parts.

It is evident from these results that to some extent the placing a piece of rubber thread in an oil for a day or two, and measuring and weighing it, may become of use as a test for different oils, or for adulteration of oils.

The threads after being removed from the oils and other liquids (after being immersed for 4 days) were

placed in glass tubes, which were afterwards filled with oxygen, and hermetically sealed and placed in a bath at 200° F.

After six hours the pieces of rubber saturated with the following oils had become quite liquid:—

Tallow Oil.	Solid Palm-nut Oil.
Solid South American Kidney Tallow.	Melted Palm-nut Oil.
Melted South American Kidney Tallow.	Olive Oil (Saville).
Pure American Neats-foot Oil.	Olive Oil (Boiled).
Pure English Neats-foot Oil.	Refined Cotton-seed Oil.
Melted Palm Oil.	Rape Oil.
Melted Bleached Palm Oil.	Pure Oleine.
	Rancid Gallipoli Oil.
	Turpentine.
	Paraffin Oil.

The following oils partially liquefied the rubber after 6 hours in oxygen at 200° F.:

East Indian Fish Oil.	Solid Palm Oil.
Pale Seal Oil.	Solid Bleached Palm Oil.
Sperm Oil.	

The following oils, etc., appeared to the eye not to be altered after 6 hours in oxygen at 200° F.:

Pure Cod-liver Oil.	Oil of Cloves.
Solid Bonny Palm Oil.	Mixture of equal parts of
Melted Bonny Palm Oil.	Rosin and Cod-liver Oils.
Cocoa-nut Oil.	Naphtha.
Castor Oil.	Benzene.
Raw Linseed Oil.	Carbon Disulphide.
Rosin Oil.	Benzoline.
Mineral Oil.	Alcohol.
Creosote Oil.	Ether.
Butter Fat.	Pyroligneous Acid.
Water.	Acetic Acid.
Free Acids from Castor Oil.	

After continuous heating for 24 hours. The following, which were partially liquid, or not altered after 6 hours, had become completely liquefied:—

Sperm Oil.	Rosin Oil.
Solid Palm Oil.	Mineral Oil.
Solid Bleached Palm Oil.	Butter Fat.
	Mixture of Rosin and Cod-liver Oil.
Solid Bonny Palm Oil.	Naphtha.
Melted Bonny Palm Oil.	
Cocoa-nut Oil.	

After 8 days' continuous heating, East Indian fish oil became liquid, whilst the remainder became hard, not having altered materially as judged by the eye, but they had become hard by the prolonged heating and oxidation:—

Pure Cod-liver Oil.	Benzene.
Castor Oil.	Benzoline.
Fatty Acids from Castor Oil.	Carbon Disulphide.
Raw Linseed Oil.	Pyroligneous Acid.
Creosote Oil.	Acetic Acid.
Water.	Ether.
Oil of Cloves.	Alcohol.

Ozonised air has but little action on unstretched or unstrained rubber, but it acts very rapidly on rubber in the stretched or strained condition.

It would be valuable to have some reliable but rapid tests for discovering whether indiarubber manufactured at different times is up to any given standard so far as length of life is concerned. Over-vulcanised rubber hardens rapidly by oxidation, although there are other things in the nature of the rubber which appear rapidly to determine its decay. I have obtained some interesting relative results by placing rubber threads, stretched on a piece of wire gauze, which was placed over a vessel containing turpentine. The ozone and peroxide of hydrogen, which is produced from the turpentine, determine the decay of the rubber after a few weeks, but it might perhaps be employed by putting the rubber threads to be tested side by side in a stretched condition on a frame, and placing the frame thus charged in a tube heated to a constant temperature, of say 150° F., which

might easily be done by aid of a thermostat, and allowing a little turpentine vapour to constantly pass up the tube and impinge on the thread, or other form of rubber suspended in the heated tube, and then to try their relative strength after any given time.

I have to thank my assistant, Mr. William L. Gadd, F.C.S., for the very able and careful manner in which he has worked out the experiments on the action of oils and other liquids on indiarubber.

\*\*\*\*\*

*The Second Meeting of the Session was held on Tuesday, December 1, 1885, in the Rooms of the Chemical Club, Victoria Buildings.*

IVAN LEVINSTEIN, ESQ., IN THE CHAIR.

# ADJOURNED DISCUSSION ON MR. WM. THOMSON'S PAPER, "THE DECAY OF INDIARUBBER."

THE CHAIRMAN, in opening the discussion, explained that as Mr. Thomson, at the last meeting, had not sufficient time to do more than give from memory an abstract of his paper, if he desired, he might bring forward any new points before opening the adjourned discussion.

Mr. THOMSON then referred to some of the parts of his paper, which he had not time to give at the last meeting.

Mr. GRIMSHAW: I confess my inability to see where the author and Dr. Burghardt are at issue. The contention of the latter seems to be that with much oil present the oxidation of the rubber proceeds so far as to liquify it, and that when little oil is present the oxidation renders the rubber occasionally hard and brittle. With this view I am inclined to agree. If strips of pure or vulcanised indiarubber be coated with boiled linseed oil, and maintained at a temperature of 50° C. for a day or two, they become hard and brittle, and assume a sort of burnt appearance. I think that indiarubber is porous, for it certainly absorbs oil and even water, and that this possibly is favorable to its oxidation. In a paper by Dr. Chandler, of Columbia College, New York (*Indiarubber and Gutta-percha Trade's Journal*, vol. xi. p. 85, November 4, 1885), the following figures are given:—"In 30 days thin sheets of caoutchouc absorbed from 18.7 to 26.4 per cent. by weight of water, and the volume increased about 15 per cent. In 8 days similar sheets absorbed 18 per cent. of anhydrous alcohol, and increased in volume 9.4 per cent." There are two ways of making the thread such as Mr. Thomson used in his experiments. In one the masticated rubber is formed into a solid block, then cut into thin sheets, which are again cut into strips of square section. In the other, a solution of rubber in naphtha is spread on sheets of cloth, and allowed to dry. The thin covering of rubber thus obtained is stripped off and cut into threads or strips. This latter process is most commonly employed, because it has been found that threads so made last longer than those made by the other method. I attribute this to the greater porosity of strips cut from a solid block. We ought to have more analyses of indiarubber and gutta-percha. Of indiarubber we have some by Faraday, some in Miller's Handbook of Chemistry, and those made by Dr. Burghardt, and quoted in his paper on the subject.\* Of gutta-percha, to the best of my belief, there are none at all.

Mr. ROWLEY: I understand the author to state that oil has little or no effect on rubber at the ordinary temperature. I have been engaged in the manufacture

for thirty years, and I cannot agree with him. Waterproof cloth is made by spreading a layer of rubber, which has been dissolved upon a piece of woollen cloth, known in the trade as "tweeds." Finishers of tweeds use a small percentage of oil in dressing, but even a very small percentage suffices to injure the material for waterproofing purposes. 4 or 5 per cent. of oil, especially such oils as are liquid at ordinary temperatures, suffices to decompose the finest indiarubber in about six weeks, when it becomes quite sticky. It is well known that Para rubbers are the best, and that African rubbers are much inferior to them. Is it possible to improve the latter by any chemical process? As regards the cells or pores said to be in the rubber, is it not likely that these are due to the removal of sulphur by the caustic soda process?

Mr. GRIMSHAW: I would like to add that woollen cloths, which are used for Macintosh making, are not dressed with pure vegetable oils, but with a mixture containing from 10 to 20 per cent. of mineral oil. It is this mineral oil which dissolves the rubber, and account must be taken of the amount present in forming any conclusion as to the causes of oxidation.

Mr. DAVIS: I can endorse Mr. Grimshaw's remarks. There is a large trade in paraffin oil for this purpose.

Dr. BURGHARDT: I am very pleased to see that Mr. Thomson has carried his investigations further than I anticipated at the last meeting. I can only say that he has worked out his experiments in a manner different from my own. While he immersed the thread, and kept it in oil for a time, and got a series of results which are interesting, I take it that my results are more practicable from a commercial point of view, as showing the cause of damage to indiarubber in the way of trade. I applied the oil on the surface, and exposed it to the air. Mr. Thomson obtained a sticky kind of decomposition with an excess of oil, but in my experiments, with a small quantity of oil, I reached the sticky stage first, and later on a hard condition, and if Mr. Thomson had allowed his experiments to continue, I have not the least doubt that the indiarubber would have become resinous, and had he analysed it, he would have found that the oxygen had very much increased.

Mr. CARPENTER: I think that Dr. Burghardt and Mr. Grimshaw's remarks as to the resinification of indiarubber may help to throw some light upon the subject from another source. Mr. Grimshaw states that if indiarubber be coated with linseed oil it becomes brittle, hard and rotten, whilst Dr. Burghardt refers to the softening effect produced by the oil. I think that temperature has an influence.

Mr. THOMSON said in reply: It is possible that by placing oil on indiarubber it will become first soft and afterwards hard, but that, in my opinion, is simply due to the fact of using a drying oil. Otherwise, the indiarubber will remain soft and sticky for many years. Mineral oils are among those which have the least action on rubber, so far as oxidation and softening are concerned, and if it be necessary for woollen cloth, which is to be used for Macintosh, to contain any oil, the mineral oil, which Mr. Davis says is much used for treating woollens, is one of the least objectionable, whilst cotton-seed and olive oils would be among the most injurious. The least objectionable of all would, of course, be castor oil. I agree with Mr. Rowley's suggestion, that by submitting the vulcanised rubber to a boiling solution of caustic soda, the minute particles of sulphur in excess would be removed and air cavities left. These air-cells would then aid in bringing about more rapid decomposition of the rubber than would be the case if the sulphur were not removed. Mr. Rowley also mentions that

\* This Journal, ii. 119-122.

he thought that about 5 per cent. of oil, if contained in the tweeds upon which the rubber is spread, would be certain to determine its decay. My experience has been that a much smaller quantity of oil will bring about that result, an amount a little under 1 per cent. being sufficient to make the thin layer of rubber between two layers of tweed soft, sticky and useless, and this is rapidly brought about at a rather high temperature, say 100° F. Mr. Rowley gave a good practical suggestion as regards the difference between Para and African rubbers. No doubt some of the constituents of the African rubbers induce oxidation and decay, and it is very probable that these might be removed, and the quality thereby improved.

—♦♦♦♦♦♦♦♦♦—

#### DISCUSSION ON MR. DAVIS'S PAPER ON THE VALUATION OF CRUDE NAPHTHAS OF COMMERCE. (THIS JOURNAL, iv. p. 645.)

MR. LEVINSTEIN quite agreed with Mr. Davis that the usual method of estimating the value of crude naphtha did not accurately show the commercially valuable constituents of that complex body; but he was afraid, on the other hand, that the test he recommended would never be accepted by the trade. In Mr. Davis's process the crude naphtha was first treated with twenty per cent. by weight of concentrated sulphuric acid. Such a large quantity of acid would inevitably absorb a considerable amount of the aromatic hydrocarbons, and the results would therefore give an unjust advantage to the buyer as against the sellers of this article.

MR. THOMSON asked if the author believed in the commercial test usually employed for testing naphthas—viz., by distillation at the rate of two drops per second? Also whether his method would give more accurate results in respect to the separation of liquids of one boiling point from that of another?

MR. WATSON SMITH thought that, even supposing the more usual amount of sulphuric acid for washing the naphtha (viz., five to six per cent. by volume) were adopted (of course employing a very thorough system of agitation), then Mr. Davis's method would yield results which would scarcely be acceptable, he was afraid, to those buyers who did not employ dephlegmating columns, and condensing apparatus of so complete a character as those used by Mr. Davis himself, and the employment of which was apparently presupposed in the method of estimation offered.

MR. DAVIS: In reply to the remarks made by the Chairman, I admit that I use more acid for refining than most rectifiers, but in my case it does not matter, as I recover, in actual working, the aromatic hydrocarbons which the excess of acid takes up. My reasons for using more are:—First, when entering the market with my benzene, I was told that the Germans washed their benzols better than the English. I obtained samples from Germany and found this was true, and thereupon resolved to eliminate from my benzols the "light stuff" which ordinarily is left in. Secondly, if you operate in the laboratory, with the same proportion of acid used on the large scale, it is impossible to produce similar results, for in the laboratory the quantities used are small, and the heat of the reaction is soon dissipated; while on the large scale there is a great bulk of liquid which is kept for a time in contact with acid at a very considerable temperature. The proportions of acid I have given for use in the laboratory will yield results comparable with those obtained on the large scale when the usual quantity of acid is employed—viz., ten

per cent. of the crude naphtha. In reply to Mr. Thomson's query, respecting the distillation test, I think it to be as good a one as can be devised for finished benzols. The test prescribes that the contents of the retort or flask are to be distilled as fast as they can be, so that the distillate shall run in separate drops, and if this is properly carried out there should be no difference in the results of different operators working apart with varying apparatus; but if a less speed be adopted, a low result will be obtained, as the upper part of the flask or retort will not be fully heated, and will act as a rough kind of dephlegmator.

—♦♦♦♦♦♦♦♦♦—

#### THE VIOLET STAINS FREQUENTLY APPEARING ON SIZED COTTON CLOTH.

BY WATSON SMITH,

*Lecturer on Chemical Technology in the Victoria University, Manchester.*

THE above defect, as it is regarded (though at once and easily removed by washing), was first brought before my notice, about six months ago, by one of the largest and most respected firms of grey cloth manufacturers in this city.

I was requested to investigate the matter and to co-operate with the firm in question, in endeavouring to overcome the difficulty.

It should be mentioned that about a year ago the same firm consulted me as to the safest materials to employ for size-mixing, so as to avoid the risks of mildew. I had recommended that a large proportion of starch (farina) should be used, as being free from nitrogenous matters, and so less likely to favour the development of mildew than a mixture consisting largely or entirely of flour, a substance which is nitrogenous.

I have recently experimented with two samples of size, differing only in that the one contains flour and the other a mixture of flour and farina, in which the latter predominates. They were placed in similar bottles, and these were then corked and left for some days. On opening both bottles the flour size was found with a patch of mildew about the size of a sixpence on its surface, and with a mouldy smell, whilst the size made with farina was not in the slightest mouldy nor had the least smell of mouldiness. Four days later the farina size began to show green spots little larger than mere points. The mould in the flour size had meanwhile considerably developed.

This experiment is by no means irrelevant to the case, as will subsequently appear. The firm stated that for the first six months of this year it had used farina size mixed somewhat as follows: Flour, 560lb.; farina, 672lb.; China clay, 1344lb.; Epsom salts, 672lb.; zinc chloride solution, 20galls. All the cloth sized with this mixture was perfect as regards freedom from stains. Yet, the following month this firm spoiled all the cloth it made with stains, but on altering the mixture in such wise as to eliminate the farina almost entirely (flour, 1400lb.; farina, 224lb.; China clay, 1344lb.; Epsom salts, 672lb.; zinc chloride 36galls.), and later on by removing the farina entirely, almost complete exemption from the stains was secured.

The violet stains referred to, first appear in the warps after sizing and drying, but they show more when the pieces are woven, and are then seen running along the warp threads of cloth in which they appear, and so are not to be confounded with accidental stains of other kinds. They cannot usually be seen by gaslight, and are only clearly discernible when the

cloth pieces are illumined by a top-light, a north-light being considered best. However, here and there in certain pieces, some few stains occur that might be seen even by bright gaslight, but they would not appear violet, but merely dark. They are at once discharged by souring the parts with dilute hydrochloric acid, or even a less dilute acetic acid. Alkalis discharge the violet, leaving light yellowish or yellowish brown stains. The violet stains are easily removed on washing the cloth with soap and water.

The firm which consulted me, informed me that the staining of the warps had been attributed to the presence of the small fragments of the cotton-seed shells in the threads of the warps to which they adhere. The notion seemed to be that these seed fragments contain some colouring matter which exudes in the sizing process, and so stains the warps threads, the seed fragments being technically said to "bleed."

This idea I have proved to be false; the seeds in neither kernels nor shells, contain any colouring matter beyond the usual brown or brownish yellow insoluble matter peculiar to ordinary dried seeds and husks; certainly no blue or violet colouring matter.

I now began to think of tannin in the seeds, and accordingly I examined seed shells and kernels separately for this principle, and found that the shells contain notable quantities of it, whilst the kernels contain only slight traces. If a parcel of cotton warp be examined, the fragments of seed shells adhering to the threads will be soon perceived, and usually I have found on decolourising a violet stain with a drop of ammonia, not only the change to a faint yellow, but a minute fragment of seed shell, forming, as it were, the nucleus of the stain; but the latter is by no means always the case. If a number of seed shells and kernels, finely cut up or ground, be separately boiled for some time with dilute alcohol, light brown solutions are obtained. That of the shells shows by its reactions with solutions of ferrous and ferric salts that tannin is present in considerable quantity; that of the latter, that tannin is present, but only in traces.

Iron is present in the ash of cotton, but I did not consider that of much importance, as it would not be in a condition to give the reaction with tannin. On examining the cotton web I found this contains but little iron, whereas the sized warps contain much iron. Procuring samples of water used in mixing the size of the zinc chloride, farina, flour and China clay, and examining them, besides inspecting the apparatus in which the size was prepared, I found the water used was ferruginous; the zinc chloride contained much iron; the farina was an exceedingly pure and beautiful preparation; the China clay very white and of the best quality, and free from iron in a condition to act on tannin; the mixing vessels were of iron, but were afterwards replaced by wooden ones. The water was also changed, and water from the city-supply used.

The conditions were consequently as favourable for the production of violet or really grey spots or stains, as in the case of cloth prepared with iron mordant, and then taken through a sumac bath. That the warps and cloth actually do contain iron, and that at the time of sizing, this iron being more or less in a soluble condition would render the warps extremely sensitive to minute traces of tannin in the shells of the cotton seeds, it will be very easy to show you in an experiment or two. This piece of grey cloth, I shall first sour with very dilute warm hydrochloric acid to bring the iron in it, now for the chief part insoluble as oxide, into the soluble condition it was in when the warps were sized; the zinc chloride used was also slightly acid. I then pass through a bath of

very dilute ammonia, to remove excess of acid, and now after rather removing some iron than adding any, I place a drop of tincture of gall-nuts on one part of the cloth, and a drop of tincture or decoction of our seed shells on another part, and the blue grey or violet spots show that tannin is present alike in both cases, and that the cloth at the time of sizing is very sensitive to such presence. Without such preparation, the cloth, dry as it is, will even give faint violet or grey stains with decoction of seed shells.

If I crush a minute fragment of ferrous sulphate (coppers) on the cloth, and add a drop of seed-shell decoction, the violet stain at once appears, after drying by the application of a warm glass plate or tube. There is no doubt that the rollers of the sizing apparatus, the upper one of iron, the lower one surrounded with layers of flannel, in removing the surplus size from the warps, also squeeze out or cause to exude tannin from the shell fragments. There are two possible remedies: (1) To remove all seed shells from warm threads before sizing. (2) To remove iron from all the materials. Both these remedies are very difficult to apply; the first on the whole, I imagine, would be most feasible, but it would involve special machinery. However, with such a firm of engineers and machinists in our city as Messrs. Mather & Platt, whose machinery is to be found throughout the world wherever cotton is spun and woven or calico printed, the problem should be one easily solved by means of some super-added device in the spinning machinery of our cotton mills. Thus, I could imagine warps presented to the sizer quite free from adhering seed fragments. The attempt to keep iron away would mean the constant application of attention in many directions, to keep the tannin away would mean its concentration on one point only. But I have said that when flour is exclusively used, not nearly the trouble is experienced in keeping the stains from view. I say from view, for I believe they are always more or less present.

We come now to consider another question—viz., that of what I will call the "covering power" of the size used. As you know, on boiling up starch and water a transparent solution is obtained—starch paste; this on drying, yields a more or less transparent coating. On sizing with farina therefore, a kind of starch paste is produced more or less transparent, and on drying, the transparency may be such that the "stains" from the seed shells show up through the size. No doubt the addition of large quantities of China clay would confer sufficient body and "covering power" to the size, to give a covering opaque as regards the "stains" so that they shall not show. But the firm I have referred to has always had a name for cloth of a high grade, and it does not wish to use more clay than it has always used before.

Flour gives a paste which is opaque, has considerable body, and on drying yields a coating possessing very considerable body or covering power. But then, as I have already stated, flour size is most apt to mildew. We see now that the manufacturer producing the highest grades of cloth, and using farina size to keep away the danger of mildew, has the greatest difficulties in his way, as far as these seed stains are concerned. With heavier sizing involving the use of more China clay and other materials, it is possible to cover up these stains, even using a size chiefly made with farina.

Yet, the agents and buyers abroad, in China and elsewhere, refuse cloth showing these stains, faint though they be, and practically harmless, possibly mistaking them for mildew in its incipient stages. The first wash with alkaline soap and water removes both the size and the seed stains, the alkalinity of the soap being quite sufficient to remove them. It is not

irrational then to refuse an article of a good substantial make, weight for weight, containing the maximum of real textile fibre, and to prefer one containing less cloth and more size and China clay, because free not from the *realities* but the *appearance* of the stains in question—these being, as stated, removed in the first washing with alkaline soaps and never reappearing. The firm I have referred to has now many thousand pieces thus rendered unsaleable in the market. I well know the demand regulates the supply; the kind of demand also regulates the character of the supply, and so "wisdom is justified of her children."

Were I judging a parcel of cotton cloth delivered to me, I should argue from the appearance of seed-stains that a light sizing had been adopted, and that probably farina or starch size had been used, and hence that I was getting at all events plenty of substantial cloth, and not size for my money. I have found that these stains are not stains in the size, but in the cloth, for on pouring a drop of my decoction of the seed husks on a little size spread out on a porcelain plate I get no slate colour or violet patch produced, as I do on repeating the experiment with a piece of cloth. Hence these stains are in the cellulose fibre and show up, or do not show up through the size. Another idea before I conclude. We know that the various astringents vary in the amounts of tannin contained in them very considerably, and we know also that in one species grown under very different conditions of climate, etc., the amounts of tannin contained may vary just as much in the different varieties of that species, and in some years also the amounts of tannin will even vary in the variety, growing in the same locality, from the amounts in other years. Thus Aleppo galls contain from 60 to 70 per cent. of tannin, whilst English gall-nuts, as I determined in 1869, contain not more than from 20 to 23 per cent. of tannin. Now, is it not possible that also the seeds and seed shells of cottons grown in different climates and under different conditions of country, soils, water, etc., may also vary in the amounts of tannin contained? May, *e.g.*, the cotton-seed shells of American, Indian, and Egyptian cottons not possibly vary considerably in the above respect, and so cause extreme trouble and anxiety to certain cloth manufacturers and sizers, from which others may be exempt? It seems to me the question is worthy of a special inquiry, for there is no doubt that at one period a manufacturer is apt to be assailed with difficulty in the direction named, which causes him great expense and trouble, whilst at another period he works without trouble or anxiety, and in neither case can he account for his position. I am informed positively that this seed staining comes like a veritable pestilence upon the cloth sizer and manufacturer at periods and seasons, and then may leave him again, and so on. I really think that some experiments should be made, and if the various buyers of raw cotton in this city would only place at my disposal cotton seeds from cotton of various growths and countries, I will undertake to ascertain what amounts of tannin are contained in them, and if, and to what extent, these amounts of tannin vary. Thus conditions being ascertained, remedies could be applied with more effect.

#### DISCUSSION.

Mr. GRIMSHAW suggested that cellulose had a natural affinity for these mordants, and left the China clay free from iron. With all the care that users of size might take, they would hardly be able to obtain it free from iron when they purchased it ready to put on the cloth. If they were to render the size alkaline

or neutral, would it not lessen the risk of having these stains?

Dr. BURGHARDT could confirm the author's explanation from his own experience. A Manchester firm had sent him some cloth with black specks on it for examination, and these specks were to be seen just where the pieces of cotton-seed shells had adhered to the cloth. The cloth being full of iron—on the warp particularly—the author's explanation seemed to him conclusive.

Mr. WM. THOMSON stated that he had also examined the stains in question. He had tried to produce similar stains by means of the shell of the cotton seed upon yarns which were free from all but traces of iron. On submitting the yarn with the cotton-seed shell attached to the action of hot water, of steam, and of different sizing compositions, he had found that the stain was produced strongly in each experiment. He had, therefore, come to the conclusion that the best way of preventing the occurrence of such stains was to free the cotton perfectly from husks and shells by using the necessary machinery. The author had told them that the shell of the cotton-seed contained tannic acid, and that this combined with the iron contained originally in the yarn or in the size (probably after absorption by fibre), forming tannate of iron, to which he considered the violet stains due. The author had also pointed out that the husk of one kind of cotton plant might be more liable to produce stains than the husk of another. This was not difficult of proof, if some cotton spinner would supply the requisite varieties of husk, and he thoroughly agreed with the author in urging investigation as to the relative amounts of tannic and gallic acids, and colouring matter in the various samples.

The CHAIRMAN congratulated the author on having solved the mystery of the stains. The belief among the Chinamen that these stains resulted from incipient mildew, had been a constant source of vexation and loss to shippers for years.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held December 9, 1885, in the College of Science.

MR. B. S. PROCTOR IN THE CHAIR.

Dr. BEDSON wished to make a correction of a statement contained in his note read at the last meeting. He had there said that the gas from the Wieliczka mine consisted of marsh gas only. This was based on an analysis of the gas by Heinrich Rose. Since

then he had been able to find a much more recent analysis of the gas by Bunsen, as follows :—

Marsh Gas .....	84.6
Carbon Dioxide .....	2.58
Oxygen .....	2.90
Nitrogen .....	10.35

99.53

The gas was obtained from that particular layer of the Wicliczka salt which decrepitates on solution in water, and he believed the sample was collected by dissolving the salt and catching the gas set free.

Mr. JOHN PATTINSON drew attention to the fact that the nitrogen and oxygen in this sample were nearly in atmospheric proportions. He said that this was very different from the Middlesbrough samples analysed by Dr. Bodson, which consisted almost entirely of nitrogen. Regarding the source of this nitrogen, he referred to statements of Dr. Angus Smith in some of his reports, to the effect that nitrates in contact with organic matter are reduced to free nitrogen, the oxygen being used to burn carbon and hydrogen of the organic matter.

## ON THE CONVERSION OF CALCIUM HYPOCHLORITE INTO CALCIUM CHLORATE.

BY G. LUNGE.

In the manufacture of potassium chlorate the first step consists in passing chlorine through milk of lime. This at first produces a solution of calcium chloride and hypochlorite, which is changed into chlorate by continuing the current of chlorine at a higher temperature. It is usual to reduce this change to a simple re-arrangement of the constituents of six molecules of bleaching powder,  $6\text{CaOCl}_2 = 3\text{CaCl}_2 + \text{Ca}(\text{ClO}_3)_2$ ; but I have already some time ago ("Manufacture of Sulphuric Acid and Alkali," vol. iii. p. 304) pointed out that the above reaction does not take place completely and without considerable loss of oxygen, except in presence of an excess of chlorine, although that chlorine does not appear in the equation. In order to acquire a more accurate knowledge of this point, the following experiments were carried out in my laboratory by Dr. Landolt :—

### A. Behaviour of Bleaching Powder Solutions when Simply Heated.

A strong, clear, solution of bleaching powder was heated, by means of a calcium chloride bath, in a flask provided with reflux-cooler, thermometer, and siphon-tube; the upper end of the cooler was closed by an indiarubber ball, which, when compressed, served for obtaining samples through the siphon-tube whenever required. The solution was first heated to  $50^\circ\text{C}$ , and was kept at that temperature for an hour before taking a sample; it was then successively heated to  $60^\circ$ ,  $70^\circ$ ,  $80^\circ$ , and  $90^\circ\text{C}$ , each time for an hour, and analysed. Subsequently it was heated to its boiling point,  $101^\circ\text{C}$ , at which samples were taken after intervals of  $\frac{1}{2}$ , 1, and 2 hours respectively. In the following table the results are calculated, putting the total chlorine = 100; column *a* shows how much of it was found as "bleaching chlorine" (*i.e.*, one molecule of hypochlorite and one of chloride), column *b* shows how much was changed into chlorate, adding to the chlorine of the chlorate itself that of 5 molecules of chloride; column *c* shows how much further chloride had been formed by the decomposition of chlorate with loss of oxygen.

	<i>a</i> Bleaching Chlorine.	<i>b</i> Chlorate = 5 mols. Chloride.	<i>c</i> Chloride formed by decomposition.
Solution employed at $15^\circ\text{C}$ .	96.21	3.76	—
Heated 1 hour .. 50	95.95	4.05	—
Another hour .. 60	95.80	4.20	—
" .. .. 70	94.41	5.10	0.49
" .. .. 80	90.00	6.31	3.69
" .. .. 90	83.33	11.54	5.08
" 1 hour .. 101	66.70	17.23	16.07
" 1 .. .. 101	57.81	20.98	21.18
" 1 hour .. 101	42.09	26.98	30.93

We notice that after gradually heating up to  $60^\circ$  for three hours no chlorate worth mentioning had been formed; this formation only sets in after heating to  $70^\circ$ , and more strongly after another two hours' heating up to  $90^\circ$ ; but even after two hours' boiling, when the heating had altogether lasted seven hours, not much over a quarter of the chlorine originally present has been employed to form chlorate.

So soon as chlorate is formed some other part of the bleach is decomposed into chloride and oxygen, and in the end this reaction takes place to a larger extent than the formation of chlorate. If we had heated for many hours, no doubt all bleaching chlorine would have vanished, but much less than half of it would have been used up for forming chlorate, more than half being destroyed with loss of oxygen. Hence it is evident that the conversion of calcium hypochlorite into chlorate by simple boiling is a very unprofitable process, which ought not to occupy the first place in the manufacturing operations.

### B. Heating a Bleach Solution saturated with Chlorine.

The operation was carried out as in *a*, except that the liquid was first saturated with chlorine (free from hydrochloric acid), and that the expelled chlorine was allowed to escape. Since this took place but gradually, I do not tabulate the results as in the last case, but I quote the percentages of chlorine in the liquor as found: thus, column *a* shows the bleaching chlorine of the bleach solution originally employed along with the chlorine passed into the solutions; column *b* that employed to form chlorate (*i.e.*, six times that of the chlorate formed), *c* the sum of both of these. (See table on next page.)

Evidently saturating the solution with chlorine converts a large proportion—say seventy per cent.—of the hypochlorite into chlorate already at  $15^\circ\text{C}$ ; two hours' heating to  $40^\circ$  increases this only slightly; above that temperature the change takes place rather more rapidly, but quite regularly, and it is entirely accomplished at the boiling point after  $7\frac{1}{2}$  hours' total heating, for we now find 2.43 per cent. of chlorine as chlorate + 5 chloride, whilst we had originally altogether 2.45 per cent. of chlorine. The slight quantity of "bleaching chlorine" still found is undoubtedly mechanically dissolved chlorine, which slowly disappears by further boiling. The figures prove that no decomposition with loss of oxygen had taken place in this case, so that the presence of free chlorine prevents the reaction  $\text{CaOCl}_2 = \text{CaCl}_2 + \text{O}$  from taking place.

### C. Heating a Bleach Solution in a Continuous Current of Chlorine.

This was done in order to try whether under these circumstances the conversion would take place more quickly and at a lower temperature than when merely once for all saturating the liquor with chlorine. It would be of no use in this case to quote the figures for "bleaching chlorine," since continually fresh chlorine was being introduced into the liquid. I therefore merely quote the percentage of chlorine in the liquid found by analysis as chlorate + 5 molecules of chloride.

Original solution at 15° C. contained 0·12 per cent. Cl as Chlorate.

The same after passing in Chlorine at 15° C. 1·02 per cent. Cl as Chlorate.

Heated for an hour to 30° C. 1·02 per cent. Cl as Chlorate.

Another hour to	35	1·08	"	"	"
"	40	1·08	"	"	"
"	45	1·11	"	"	"
"	50	1·11	"	"	"
"	55	1·20	"	"	"
"	101	1·56	"	"	"
"	101	1·62	"	"	"

Here also the current of free chlorine causes a considerable formation of chlorate even in the cold, and this increases but slowly when gradually heating up, in spite of continually passing in more chlorine, certainly not any more than in the preceding series of experiments, where only in the beginning an excess of chlorine had been provided. Whilst in the former

seem to represent these reactions in the most probable way:—

That is to say, the free chlorine only serves as carrier of the oxygen of two molecules of calcium hypochlorite to a third molecule of the same, whereby the two former molecules are reduced to chloride, the third molecule is oxidised to chlorate, and the free chlorine first entering into the process is again completely liberated in the end.

### D. Conversion of Hypochlorite into Chlorate at the Ordinary Temperature.

In the first stages of the series B and C we had noticed that a considerable quantity of chlorate was formed by merely passing chlorine into a solution of bleaching powder at the ordinary temperature. In B this amounted to seventy per cent. of the theoretically possible quantity. This suggested the experiment of trying whether the conversion might be made perfect by simply prolonging the contact with chlorine at the ordinary temperature for some length of time.

A bleach solution containing 1·75 per cent. bleaching chlorine and 0·12 per cent. of chlorate-chlorine (i.e., chlorine belonging to chlorate + molecules of

	a Bleaching Chlorine.	b Chlorate + 5 Chloride	c Sum Total.
Original solution at ..... 15° C.	2·36	0·09	2·45
The same saturated with Chlorine at 15	1·85	1·78	3·63
Heated one hour to ..... 30	1·78	1·78	3·56
Another hour to ..... 40	1·68	1·83	3·51
" " " " " " " " " " " " 55	1·47	1·94	3·41
" " " " " " " " " " " " 60	1·26	2·01	3·27
" " " " " " " " " " " " 70	0·98	2·13	3·11
" " " " " " " " " " " " 80	0·72	2·23	2·95
" " " " " " " " " " " " 90	0·12	2·35	2·77
" half-hour to ..... 101	0·17	2·43	2·60
" " " " " " " " " " " " 101	0·11	2·48	2·59
" hour " " " " " " " " " " 101	0·07	2·49	2·56

series after nine hours the quantity of chlorate was twenty-seven times that originally present, in the second series this amounted to only 12½ times. It is not impossible that the continued current of chlorine carried away some of the hypochlorous acid liberated in the process, and thus diminished the formation of chlorate.

In any case the continued passing of chlorine through the liquid is useless, perhaps even injurious; it is sufficient if always a slight excess of chlorine is present.

We understand this fact quite well from a theoretical point of view, since none of the free chlorine is used up in the reaction. Hitherto no other explanation of that reaction has been given but that mentioned in the above-quoted place (vol. ii. p. 890)—namely, that first of all, the action of an excess of chlorine on the hypochlorite leads to the formation of free hypochlorous acid (a well-known fact), and that the latter converts another quantity of hypochlorite into chlorate. The following equations

(chloride) was saturated with free chlorine and allowed to stand at 15°. It showed—

After 24 hours 1·26 per cent. Chlorine as Chlorate + 5 Chloride.

" 48 " 1·32 " " " "

The last figure, deducting the original 0·12, amounts to 1·20—that is, sixty-nine per cent. of the quantity theoretically obtainable from the hypochlorite present. This shows that the conversion at the ordinary temperature proceeds almost at once to the limit of about seventy per cent., but afterwards makes very slow progress, so that it is impracticable to wait for its completion without heating.

The above-described experiments seem to point to the following conclusions:—The most favourable way of converting hypochlorite into chlorate is not either a mere raising of the temperature, or a mere excess of chlorine, by themselves, but both these conditions must be fulfilled at the same time. A large excess of chlorine is useless, perhaps injurious, for the yield of chlorate. On the large scale it is

unnecessary to raise the temperature artificially, the heat produced by the reaction itself being sufficient to complete it. A rise of the temperature without the presence of free chlorine is most injurious, because then a great deal of hypochlorite is split up into chloride and oxygen; an excess of chlorine prevents this loss.

## ON THE ESTIMATION OF SULPHUR IN PYRITES.

BY G. LUNGE.

I SHOULD not feel called upon to say a last word in reply to Dr. Clark, if his last communication (*Journal of the Society of Chemical Industry*, 1885, p. 573) did not mix up several things which ought to be separated, thus producing an erroneous impression with respect to my process for estimating sulphur in pyrites. He now states that the dry process (his own process is but a slight modification of others previously known; compare, for instance, Lunge and Hurter's "Alkali Makers' Pocket Book," p. 114) was experimentally compared with only that modification of the wet process used by the Thariss chemists and Dr. Tatlock. But in his first communication, which I opposed, he speaks at length of my wet process, without saying that the "ordinary wet method," by which the analyses quoted by him were made, essentially differed from mine. To that Glasgow method, as now described by him, but to which I cannot concede the title of the "ordinary" wet method, I should certainly demur on account of the large excess of acid employed. It is not that method, it is *mine*, as described in the above Pocket Book, p. 81, of which I stated, on unimpeachable authority, that it yielded most satisfactory results, and had, in Germany, put an end to disputes between buyers and sellers. The discrepancies of half per cent., mentioned by Dr. Clark, had occurred to Fresenius' assistants with my *old* process (that is, that described in my "Sulphuric Acid and Alkali," vol. i. p. 102); and although experimenters accustomed to the process (assuredly an indispensable condition for obtaining perfect trustworthiness with any analytical process, but one not fulfilled by those gentlemen) would have obtained far more satisfactory results, I was induced to modify my process in such a way that it has been found acceptable to Dr. Fresenius himself, and to the German chemists generally. This process yields the sulphur of pyrites with an accuracy entirely sufficient for all practical purposes (the *maximum* of discrepancies not exceeding  $\frac{1}{2}$  per cent.); and it purposely leaves aside the sulphur of galena, and that combined or combinable with baryta or lime, which in some descriptions of pyrites amounts to several per cent., all of which are absolutely useless for the manufacture of sulphuric acid.

### DISCUSSION.

MR. RENNOLDSON mentioned that he had that afternoon made an experiment which agreed generally in its results with Dr. Lunge's experiments in series A. Taking a solution of bleaching powder, and boiling it until of the usual concentration for the preparation of chlorate (sp. gr. of 1.3 to 1.4), he found that, while the total chlorine was the same as before, only about 20 per cent. of the original bleaching chlorine remained as such, about 40 per cent. was converted into what Dr. Lunge has called "chlorate-chlorine," and hence oxygen must have been given off equivalent to the remaining 40 per cent. He had been surprised at this result, for though he was aware that certain reagents would evolve from bleach oxygen

equivalent to its bleaching chlorine, he had not expected that it would decompose in that way of itself.

THE SECRETARY mentioned a case which had occurred of a bottle of bleaching powder, which had been standing aside for several months, and had suddenly burst. The total chlorine was found to be the same as in the fresh bleach, and the only explanation which could be offered was that the bleach had gradually decomposed with evolution of oxygen, which had accumulated until its pressure sufficed to burst the bottle.

MR. JOHN PATTINSON, in regard to the second paper by Dr. Lunge, wished to state that he had made comparative analyses of a sample of pyrites by Dr. Clarke's method and by Dr. Lunge's method (the "new" method as described in Lunge & Hurter's Pocket Book), with the following results:—

	Clarke's Method.	Lunge's Method.
(I.)	48.97	48.88
(II.)	48.80	48.80

It appeared, therefore, that the two methods gave practically identical results, and that Dr. Clarke's contention that his method gave higher percentages than Dr. Lunge's could scarcely be upheld.

MR. J. NEILSON CUTHBERTSON IN THE CHAIR.

## ON THE REFUSE WATERS OF CHEMICAL WORKS AND OTHER FACTORIES.

BY DR. WALLACE, F.R.S.E., F.I.C., F.C.S.

DURING last Session considerable interest was excited in this Society by the announcement that a new Rivers Pollution Bill had been introduced into the House of Commons, some of the provisions of which were considered so stringent that manufacturers would have much difficulty in complying with them. The subject was discussed in considerable detail in London and at the sectional meetings throughout the country. At the meeting held here on 3rd February last, the greater part of the evening was spent in the criticism of the Bill by several authorities on the subject of River Pollution. Among others I took part in the discussion, and, going over the Bill clause by clause, endeavoured to show that while in some cases the proposed enactments were unnecessarily

stringent, in others they were decidedly too lax. I mentioned that I was at the time engaged in a series of analyses of refuse matters from chemical and other factories. These were shortly afterwards completed, and the results reported to the Town Council of this city on 30th April. The analyses amount to 47, and include 2 of town sewage, 12 effluents from dyeworks, 4 from distilleries, 2 from paper works, 2 from tar and ammonia distilleries, 2 from gut works, 4 from slaughter-houses, 2 from tanneries, 4 from skin-dressing, dyeing, and tanning works, 3 from oil refineries, 1 from a soapwork, 6 from chemical works, 1 from a brewery, and 2 from galvanising works.

I propose to-night to state, in general terms, the nature of the results obtained in this inquiry, and to make some observations on the probable effects of manufacturing refuse waters in the purity of rivers.

Of the 45 samples of refuse water (the other two being ordinary sewage) 14 had an alkaline reaction, 18 were acid, and 13 were neutral. The highest degree of alkalinity was that of a refuse water from a soap factory, which contained alkali equal to 958 grains of real soda per gallon. The largest quantity of free acid was found in a refuse water from a galvanising works, the acidity being equal to 5432 grains of oil of vitriol per gallon. The quantities of the liquids containing these enormous proportions of alkali and acid are, fortunately, comparatively small; but other samples containing considerable quantities represented large daily outflows.

A number of the liquids contained dissolved matter which was capable of being precipitated by neutralising. Thus the waste water from galvanising works contained in solution enormous quantities of iron and zinc, with small proportions of arsenic; and a liquid from a chemical work contained the following:—

	Grains per gallon.
Sulphuric anhydride.....	7457.5
Chlorine .....	4914.0
Iron .....	2177.7
Copper.....	52.4
Zinc .....	325.5

Such liquids as these will give a large amount of precipitate on being neutralised, as no doubt they will be, by mixing in the sewers or in the river with sewage and with alkaline waste waters. Again, in water discharged from distilleries, even if free from sediment, there is a large amount of gluten dissolved in lactic acid, and this gluten will precipitate if the liquid is neutralised.

Many of the liquids contain putrescible ingredients, and become very noxious by keeping for some time. Among these are the drainage from the slaughter-houses and the effluents from gut works, tanneries, and skin-dressing and dyeing works, paper works, and distilleries.

Some of the liquids evolve sulphuretted hydrogen on being neutralised. The water from heaps of soda waste are pre-eminent in this respect. One of the specimens examined was found to have a degree of alkalinity equal to 733 grains of real soda per gallon. It had a deep yellow colour, and contained sulphides of sodium and calcium, and also some sulphites and hyposulphites. The amount of sulphur in the sulphides was 913 grains per gallon, and 238 grains of sulphur were precipitated on the addition of an acid. The liquid also contains a small proportion of arsenic in the form of sulphide.

The proportion of solid or suspended matter in the discharges is very important, since these are liable to settle down in the bed of a river and produce a pestiferous mud constantly evolving offensive gases. The worst offenders in this respect are the distillers, but dyers, tanners, paper-makers, skin-dressers, and

others, are also to be credited with the admission to the sewers, and hence to the river, of a great amount of solid matter which should not, in my opinion, be permitted to leave the various works.

In 1879 I was engaged in the prosecution of a series of experiments on the chemical and mechanical treatment of sewage, for which works were established near the outlet of one of the city sewers; but unfortunately for me this sewer contained the drainage of two distilleries. At the beginning of the experiments the sewage was so much contaminated with pot-ale that it contained on one occasion 66 grains per gallon of free acid (calculated as acetic acid), and on two other occasions nearly as much. The effect was that the sewage, besides being rendered acid, was enormously increased in strength as regards nitrogenous organic matter, and that instead of 1 ton of lime per million gallons being amply sufficient for precipitation, from 33 cwt. to 2 tons were required. In most distilleries it is now the practice to add a limited quantity of lime, which neutralises a portion of the acid, and to collect as much of the suspended organic matter as can be conveniently got, press it in bags, and sell it for feeding pigs. The effluent water still contains much acid and dissolved albumenoids, and is quite unfit to be run into a sewer. It should be treated with a slight excess of lime and thoroughly settled or passed through a filter-press, and the solid produce disposed of as manure. In one lot of dried sludge made from sewage largely charged with pot-ale, the calculated manurial value was £4 9s. per ton; while the dry sludge made from the same sewage when free from that contamination, by the same process, had a calculated value of only £1 8s. 4d. per ton. In the treatment of pot-ale, a mixture of sulphate of alumina and lime causes a more rapid precipitation than lime alone, but does not present any other advantage.

There are several objections to the admission of pot-ale into sewers and into rivers. Its acidity alone is objectionable, on account of its corrosive action upon all descriptions of mortars and cements, which it gradually eats away, destroying the stability of built sewers and the jointing of pipe-drains, and permitting the sewage to get away into the subsoil. Again, if the acid liquid comes in contact with sewage which, from continued dry and warm weather or other circumstances, has become to some extent decomposed with the formation of sulphides, it will set free sulphuretted hydrogen. A case occurred a few years ago in this city, in which a copious volume of sulphuretted hydrogen was evolved and very serious inconvenience caused. Two sewers in contiguous and parallel streets conveyed to the river highly acid water, and water charged with alkaline sulphides. So long as the sewers remained tight no harm was done, at least till the foul liquids reached the river; but in course of time the acid water ate its way through its own sewer and into that containing the sulphides, and such a stench was created that the city authorities were obliged to lift and relay both sewers. Another objection to pot-ale is that it is itself highly susceptible to putrefactive changes, and in its worst form is at least 17 times the strength of average Glasgow sewage, which contains 5 grains per gallon of free and producible ammonia. The sedimentary matter existing in the pot-ale, or produced by the neutralising of its free acid, settles down very readily in the beds of rivers, wherever these are sluggish in their flow, giving rise to a peculiarly noxious soft mud which, in warm weather, stinks badly, and is generally teeming with the small red sewage worm *tubificæ vividorum*. I have seen this mud in a great many rivers receiving the discharge from distilleries. Pot-ale should not therefore be allowed to pass into

a river, even in cases where a special pipe is provided to deliver it. The addition of lime in slight excess neutralises the free acid and throws down a large proportion of the dissolved, as well as the whole of the suspended, impurities. After this treatment the clear effluent may be allowed to pass into a sewer or into a river without risk of creating a nuisance.

In regard to acid discharges generally, I am of opinion that it will in most cases be found sufficient to run the waste water over a slightly inclined bed of chalk or limestone of sufficient extent. This is done at one large chemical works in Glasgow (the acid being chiefly hydrochloric), and the results are quite satisfactory, the free acid in the effluent being only about half-a-grain per gallon.

In paper mills there are, from different parts of the process, both alkaline and acid waste water. If the whole drainage be brought into one series of settling tanks, sufficient to contain each the product of a day's working, and thoroughly mixed, such an amount of neutralisation and purification will be effected that the effluent may safely be turned into a sewer or direct into a river. The probability is, that in almost all paper mills, where the drainage is treated in this way, the final effluent will be alkaline rather than acid. Of course I assume that the "black boil" or strong alkaline liquor drained off from the cylinders in which esparto grass is boiled with caustic soda, is treated separately, and the soda recovered by evaporation and incineration. In cases where this is not done, it is hopeless to attempt to make the effluent sufficiently pure to be admissible to a river.

I have already referred to the effluent from galvanising works, and from a particular chemical work in this city, as containing an enormous amount of iron. It is chiefly in the form of protochloride, and is accompanied by a large quantity of free acid. This liquid must have a very deleterious effect on built sewers and the jointings of pipe-drains, and should not, on any account, be allowed to pass into them. The simplest method of purifying it would be to add lime in sufficient quantity to neutralise the free acid, and precipitate the oxide of iron which, after exposure to the air to convert it into peroxide, could be washed and dried, forming an ochre which could be readily disposed of to paper makers, paper stainers, linoleum manufacturers, and pigment makers, and would probably more than repay the cost of production. It would also be an excellent material for the purification of illuminating gas. The liquid would require to be considerably diluted before precipitating, and the mixture with lime exposed for some time in shallow tanks or ponds to promote oxidation. This liquid would be, in conjunction with alum-cake and lime, a most valuable agent for the precipitation of town sewage. It has been found in Coventry and some other English towns, that the addition of an iron salt, such as exists in this liquor, to the ingredients formerly used (alum-cake and lime), gives a superior effluent, with less expenditure of precipitants, to that formerly produced. Dr. Thresh, of Buxton, has recently found that a mine water containing some iron salt, when mixed in considerable quantity with sewage, causes a rapid precipitation, and gives a clear and excellent effluent. The strength of the waste liquid is such that it would bear railway carriage to any precipitation works within a distance of twenty miles, or even more; and it might be conveyed in tank waggons lined with lead, or well coated with pitch.

When waste water of this kind is run into a river, the acids are neutralised by the calcic and magnesian carbonates of the river water, and an ochrey precipitate is formed, which is most injurious to fish. Certain kinds of pit water are of a similar character,

although not nearly so concentrated; and the effect of such admixture is seen in many of our Scotch rivers, especially the Almond and its tributary the Breich Burn, from which fish, formerly plentiful, have practically disappeared.

Few manufacturing operations are more destructive to the purity of rivers than the washing of skins and hides. The effects are seen on the Molindinar Burn in Glasgow, and in the Gala at Galashiels.

When the "yellow liquor," drained off heaps of soda waste, is introduced into a river, the sulphides are gradually oxidised by the free oxygen dissolved in the water, and the greater part of the sulphur is set free in a finely divided condition, rendering the water milky. If present in large proportion, however, a portion of sulphuretted hydrogen will be set free by the action of carbonic acid, and a noxious odour will be evolved. In the case of our own river Clyde, the mud which settles down in certain places, contains always a notable proportion of sulphide of iron, the sulphur of which, or part of it, is probably derived from the yellow liquor which comes down a special pipe from the northern part of the city. I have already referred to the evil arising from an admixture of acid water in the sewers with the yellow liquor; sulphuretted hydrogen is given off in quantity, and a very serious nuisance results. When the yellow liquor is sufficiently strong it can be treated successfully for the production of sulphur. By blowing air through it a good deal of sulphite and hyposulphite are produced, and by oxidising one portion and adding another in its ordinary condition, and neutralising with hydrochloric acid, nearly the whole of the sulphur is precipitated.

In the case of Glasgow, the quantity of manufacturing refuse water is nearly nine million gallons per day, and on the average of the various samples it is about three times as strong in putrescible organic matter as ordinary town sewage. But some of the discharges that are largest in quantity are comparatively clean, so that the average of the whole nine million gallons of manufacturing waste water is considerably less than three times as strong as the twenty-seven million gallons of ordinary sewage. On the other hand, there are a number of small factories in the city which, collectively, give a considerable volume of refuse water; and there are several works beyond the city boundaries which give discharges of a most objectionable character. Upon the whole, I consider it a fair estimate to assume that the impurities found in the water of the Clyde are due to sewage proper, and to manufacturing refuse, in about equal proportions. Many of the factory discharges contain large quantities of suspended matter, and are otherwise comparatively free from impurities. In such cases, all the purification that is necessary to render the effluent admissible into the public sewers, or into the river, is the adoption of a thorough system of subsidence, aided, when required, by the addition of chemicals, as in the precipitation of ordinary sewage.

It may be well, here, to refer to legislation for the prevention of the pollution of rivers, so far as it refers to manufacturing waste products. The Act at present in force is that of 1876. The provisions in that Act are very indefinite, and are hedged about with so many conditions, that they have been found to be practically inoperative. Stated generally, the Act forbids the putting into any stream, any poisonous, noxious, or polluting liquid proceeding from any factory or manufacturing process, unless it can be shown that the best practicable and reasonably available means have been used to render harmless the poisonous, noxious, or polluting liquid. Proceedings, however, can be instituted only by a Sanitary Authority, with consent of the Local Government

Board (in Scotland, the Secretary of State). It is further provided that the Local Government Board (or Secretary for Scotland) shall not give their consent to proceedings by the sanitary authority of any district which is the seat of any manufacturing industry, unless they are satisfied, after due inquiry, that means for rendering harmless the poisonous, noxious, or polluting liquids proceeding from the processes of such manufactures are reasonably practicable and available under all the circumstances of the case, and that no material injury will be inflicted by such proceedings on the interests of such industry.

A very important section of the Act is No. 7: "Every sanitary or other local authority shall give facilities for enabling manufacturers within their district to carry the liquids proceeding from their factories or manufacturing processes into such sewers: Provided they shall not extend to compel any sanitary or other local authority to admit into their sewers any liquid which would prejudicially affect such sewers, or the disposal by sale, application to land, or otherwise, of the sewage matter conveyed along such sewers, or which would, from its temperature or otherwise, be injurious in a sanitary point of view: Provided also that no sanitary authority shall be required to give such facilities as aforesaid, where the sewers of such authority are only sufficient for the requirements of their district, nor where such facilities would interfere with any order of any court of competent jurisdiction respecting the sewage of such authority."

Under the existing law, therefore, and under existing circumstances, the corporation of a city or town are bound to admit into the sewers all manufacturing waste water, unless—

1st. The waste liquid would act injuriously upon the sewers. This effectually enables them to forbid the putting into the sewers of any liquid containing free acid.

2nd. Unless from its temperature or otherwise it would be injurious in a sanitary point of view. This enables the authority to exclude from the sewers such liquids as the yellow liquor from soda waste, and probably also such foul liquids as

Distillery waste water (pot-ale).  
Papermakers' discharges.  
Gut-work discharges.  
Galvanising-work discharges.

unless these are effectually purified by neutralising and settling, or filtration.

With regard to the Rivers Pollution Bill brought in by Mr. Hastings, Earl Percy, and Colonel Walrond, in last Session of Parliament, and which will probably be re-introduced in a modified form in the coming Session—I may say generally, after a careful study of the "standards of purity," and the analysis of the waste waters of the Glasgow factories, that only one of the whole 45 effluents would comply with these standards, and would be admissible into the city sewers or into a river. As an illustration of the stringency of some of the clauses, I may mention that one of the standards of purity is, that no liquid shall be permitted to enter a stream which contains more than seven-tenths of a grain per gallon of sulphur, in the condition either of sulphuretted hydrogen or of a soluble sulphuret. Now, one of my samples contained upwards of 900 grains per gallon in this condition; and it follows that it would not have been admissible to the Clyde, under the proposed Bill, even if mixed with a thousand times its bulk of clean water.

In regard to the general question of the pollution of rivers, whether by manufacturing refuse or by the sewage of towns and cities, there are three considerations: (1) the effect on the suitability of the water for dietetic purposes, the watering of cattle, the washing of clothes, and other primary uses, as they are called

in Scotland; (2) the effect upon fish, generally, and especially upon salmon; and (3) the effect upon the amenity of a river or its banks. Many rivers receive a great amount of impurity both from manufacturing and domestic sources, and yet cannot be described as polluted streams. Take, for example, the river Tay, which receives the whole of the sewage of Perth, a city of about 30,000 inhabitants, besides the drainage from several very extensive dyeing establishments. But this river, one of the largest, if not the largest, in the British Isles, carries such a volume of water that the impurities are swallowed up and oxidised almost immediately, and the amenity of the river is not appreciably injured. As regards fish, salmon are caught in great numbers, one of the most valuable of the fishing stations being right in the middle of the city of Perth. For drinking and other primary purposes, however, the water is appreciably deteriorated for at least a mile below the town, and hence it is proposed to purify the sewage and effluents from the dyeworks before admitting them to the river. As an example of what may be called the self-purification of a river, the Thames is a good example. It receives in its course the sewage of many towns and villages, some of them of considerable size; and yet, above London, it is so far purified that simple mechanical filtration converts it into potable water of very good quality. The condition of the Clyde above Glasgow is also fairly satisfactory, considering that it has received the drainage of the towns of Lanark, Hamilton, Airdrie, and Coatbridge, besides others of smaller dimensions; but below the city it is extremely dirty; it is totally unfit for primary purposes, fish cannot live in it, and it cannot be sailed upon without risk of causing nausea, if nothing worse. The condition of the Clyde, however, bad as it is, is not to be compared with that of the Irwell, the Bradford Beck, the Aire, and some other rivers in the manufacturing districts of England, which are little better than open sewers.

That something should be done to improve these rivers is readily admitted by all, but hitherto the difficulties of dealing with them have been so great that practically there is little improvement in their condition. It is true that some towns, such as Birmingham, Coventry, Leeds, Bradford and Leicester, have been compelled to erect works for the purification of their sewage, but in some cases the effluent falls into a river so impure that no appreciable improvement is produced. A new Act which will compel all towns above a certain size and all factories draining direct into a river to effect such a purification as is necessary, is urgently needed; but the standards of purity need not be so stringent as some of those contained in the Bill introduced in last Session of Parliament. If all suspended matter be effectually removed by mechanical or other means, poisonous substances excluded, and free acid or alkali, as the case may be, reduced to reasonable limits, that is really all that is necessary. The dissolved oxygen in the river water, aided by the microscopic organisms which are rarely, if ever, absent, will complete the purification, except in a few extreme cases where the volume of the river or stream is small as compared with that of the drainage. In the case of Glasgow sewage, I have demonstrated that when deprived by any means, mechanical or chemical, of its suspended impurities, and afterwards mixed with ten times its bulk of clean river water, it will no longer putrefy, but on the contrary will speedily become, to all intents and purposes, pure water.

#### DISCUSSION.

Prof. MILLS thanked the author for his suggestive paper, and acknowledged that he had shown great

resource in treating effluents from works. The chemical side of the problem presented little difficulty, but manufacturers had also to consider the question of space for tanks and filtering operations. With the prospect before them in the near future of the passage of some stringent measure to prevent pollution, he would advise them to look to their surroundings and see if they could acquire land for such purposes. Some years back, Dr. Angus Smith had found decided self-purification in a canal of very sluggish current; and the river Thames showed considerable chemical purification at various points of its course. This was attributed to filtration of a portion of the flow through porous soil, the water reappearing in a clarified state—farther down stream. On the other hand, during the last two years of his life, Dr. Angus Smith had instituted physiological experiments to determine the presence of germs in river water. By the use of the gelatin process he had discovered swarms of organisms in that supplied to London, and had reported to this effect to the Local Government Board, giving drawings to illustrate his results. Until this apparent conflict of opinion had been reconciled, and experiments like those of Dr. Angus Smith were instituted on a larger and more comprehensive scale, he felt that scientific men would do well to suspend their judgment. Meanwhile he would invite the attention of physiologists and sanitary authorities to this question of physiological purification, which might be far harder to achieve than mere chemical purification.

Mr. COLEMAN said that Dr. Dupré had recently addressed a report to one of the Metropolitan boards, which had been published, showing that the amount of bacterial life in rivers such as the Thames was best determined in the following way: A measured quantity of the water was confined in a glass vessel over air or oxygen, and after several days a determination was made of the amount of oxygen absorbed and converted into carbonic acid. Dr. Dupré considered this method better than estimating organic matter by permanganate of potash or any such process which arrested bacterial life—the essence of an examination being held to be the observation of the vitality of the germs which, according to their several natures, might be pestiferous or beneficent. If he remembered aright, it was also pointed out how the different kinds of germs might be approximately distinguished one from another. The *Engineer* of 27th November contained an able comment upon this report.

Mr. TATLOCK said that the paper showed in a striking light what care must needs be exercised in drafting any measure for the prevention of river pollution, and how completely the latest attempt in this direction had failed. All waste waters and discharges from chemical factories and other sources were placed on the same footing, and were to be compared with one fixed standard of organic and inorganic purity—a perfectly impracticable matter, as anyone acquainted with the variety and nature of these discharges very well knew. Purification would be dearly purchased if it involved closing works and ruining industries. He thought that in future legislation it would be best to treat all classes of works, each upon its own merits, and appoint inspectors with large discretionary powers. In his opinion legislation should follow science, and not precede it by seeking to enforce processes of purification which were at present unknown.

Mr. STANFORD asked whether he was right in his opinion that Dr. Dupré did claim to distinguish so-called pestiferous germs from harmless ones, and also whether boiling failed to destroy sewage germs while killing innocuous varieties. If that were so, a means

was now afforded for the first time of finding whether organic matter in water was dangerous or not, and this had long been a desideratum. As regarded the paper before them, he had been astonished to hear how concentrated some of the effluents from the Glasgow factories were. The idea of a liquid containing per gallon 4½ lb. of oil of vitriol being sent into the sewers was indeed alarming. No public authority could deal with such pollution as that, and all such must be imperatively checked at its source and dealt with there. Dr. Wallace appeared still to think lime the best available purifying agent. Was it not the case that the effluent from lime purification was nearly always alkaline and liable to putrefaction. In his opinion the only method capable of dealing with soluble organic impurity was to filter it through a bed of charcoal, preferably wood charcoal, and constantly revivify the filtering medium by turning. This was neither an expensive nor difficult method, provided that all matter in suspension were previously removed.

Dr. WALLACE, in reply to Prof. Mills, said that space was an important factor in chemical operations. In cases where no space was to be had upon the spot, as in many Glasgow factories, he would suggest running the foul liquids by a special pipe to a distance for treatment. As to Dr. Angus Smith's experiments on the London waters, he was well aware that a certain measure of self-purification did not entirely preclude the presence of germ life. Within the last few days he had seen results obtained by Dr. Percy Frankland upon that very water supply, showing that they contained germs in variable and sometimes considerable quantity. At the same time, such waters might be quite suitable for primary purposes, and serve well enough to sustain fish life. Dissolved oxygen acted not only on impurities introduced by man, but also on those derived from the soil. For instance, fresh Loch Katrine water contained only traces of carbonic acid, the dissolved gases consisting almost entirely of oxygen and nitrogen. After the lapse of a few weeks the water, if kept in a jar, evolves, when boiled, gases containing about 5 per cent. of carbonic acid, which showed that the oxygen of the air had been acting upon the natural impurities contained in the water. In reply to Mr. Tatlock, the absurdity of putting all rivers and localities under the same conditions had been sufficiently demonstrated in their previous discussion on the subject. He knew many instances in which the so-called pollution was purer than the stream which it was supposed to contaminate. In respect to the action of lime he quite agreed with Mr. Stanford. Free lime was poisonous to fish and liable to cause putrefaction. At Bradford the alkaline effluent from the sewage works was passed through a bed of fine breeze, which promoted precipitation in its pores of the lime in the form of carbonate, leaving the effluent nearly neutral. A slight addition of acid would serve to complete the action. Wood or seaweed charcoal would do even better than breeze for this purpose, but breeze was practically a waste product and readily obtainable in large quantities in most localities, whereas wood and seaweed charcoal were not.

(A) ON THE USE OF IRON INSTEAD OF ZINC FOR THE CONSTRUCTION OF VOLTALIC BATTERIES. (B) ON THE WASTE OF ENERGY IN PRECIPITATING COPPER SALTS BY METALLIC IRON, AS COMMONLY PRACTISED.

BY J. J. COLEMAN, F.I.C., F.C.S.

It seems very singular to me that more attention has not been bestowed upon the utilisation of iron as a

substance to be burned in a voltaic battery, seeing that the oxidation of iron, according to the researches of Andrews and Favre and Silberman, develops two-thirds or three-fourths as much heat, weight for weight, as zinc. The exact figures are these—677 as against 847, supposing the iron is used to precipitate copper sulphate solution instead of zinc. Iron has been frequently used as the electro-negative element of a battery, especially when in the passive state by contact with concentrated nitric acid. Probably the objection to its use as an electro-positive element has arisen from the earlier experimenters finding local action uncontrollable, which in the case of zinc could be obviated by the expedient of amalgamation. I have recently made some experiments in this direction. In point of fact, I have constructed a sulphate of copper cell in which the copper is used in contact with sulphate of copper, as is customary in Daniell's cell, but the zinc is replaced with iron used in contact with ferrous sulphate. I find that three of such cells connected in series decompose water, so that the electromotive force is probably what theory indicates, about two-thirds of a Daniell cell. Moreover, such a form of battery gives what the practical chemist dearly loves—viz., a chemical cycle easily worked, and restoring the materials to their original state. The solution of sulphate of iron produced by the working of the battery on evaporation and distillation yields sulphuric acid and peroxide of iron, the former ready to be combined again with the deposited copper, and the latter ready for the blast furnace to be reconverted into metallic iron. For the prevention of local actions, I find that a form of battery similar to the Medinger or Sir William Thomson battery answers, with some important practical alterations of detail, and this battery, requiring no porous cells, can be made of any size desirable.

END ELEVATION.

SIDE ELEVATION.

The foregoing words formed a portion of a recent address to the Philosophical Society of Glasgow, but since then I have had occasion to construct a constant battery for working a Ruhmkorff induction coil, employed for a lengthened series of experiments upon ozone during the months of June, July, and August of this year. The battery was constructed of twelve cells, having the following form, and worked remarkably steady for the whole period of three months, as evidenced by the length of the spark of the induction coil, which was sometimes worked for thirty hours consecutively:—*a b c d* is a copper cell, *i i i* are iron plates dipping into solution of ferrous sulphate dissolved in four parts of water. *s s s* is a layer of saturated solution of copper sulphate introduced by the funnel *f f f*, having a wide stem so as to prevent hydrostatic pressure causing current in the ferrous solution.

When the cell was thus prepared it was found that the layer of sulphate of copper solution remained without much diffusion into the sulphate of iron solution for two months.

After the iron plates *i i i* were placed in position, and the 12 cells were connected in series, the surface of the iron solution was protected from the oxidising influence of the atmosphere by a layer of oil, and the whole was allowed to remain at rest, with the exception that as the sulphate of copper became exhausted a little fresh saturated solution of sulphate copper\* was poured down the funnel *f*, and a corresponding quantity of sulphate of iron solution was drawn off at the point *x*. It was found that cast-iron plates were very unevenly acted upon; they became friable and spongy, and resembled in appearance cast iron which has been immersed for a number of years in seawater. Malleable iron plates were more satisfactory, and were easily cleaned, after being in use for a period of three months.

Mr. Bottomley has been kind enough to test one of the cells in Sir W. Thomson's laboratory, and has found the E.M.F. to be 36 of a Daniell cell. Possibly better results may be obtained, and for this reason a few more tests will be made with a few cells connected in series. Meantime it has been noted that with about 100 square inches of surface of the copper plate, the electrolytic deposition of copper in each cell amounts to about 1oz. avoirdupois in 24 hours, the electrodes being connected with thick wire.

Although the E.M.F. of this battery is small, the cheapness of the materials, and facility with which they may be obtained and restored to their pristine state in unlimited quantity, makes it worthy of some notice. There is no doubt that any method of constructing a primary battery which involves selling of a product likely to glut the markets is of little national importance, but any effort to utilise a material like iron, even although the action may be slow, or the apparatus cumbersome, is worthy of attention.

From these experiments it would appear that in

practice the consumption of iron in a primary battery would be at least 50 per cent. more than that of zinc for equal strengths of current, but on the other hand, malleable iron is only half the price of zinc, and cast iron is only one fourth its price. Primary batteries will always be more or less in demand, and when well constructed, I am inclined to think yield currents at as little cost as those produced by the dynamo, except in those cases where the motive power is at hand. Anybody with the slightest experience with machinery knows that the cost of erection, attendance, and repairs is a very serious undertaking, supposing an engine has to be run a great number of hours daily. Any extensive use of zinc, on the other hand, would soon affect its market price, as the annual consumption of the metal throughout the world does not exceed 70,000 tons. Taking into consideration the illuminating power of the 15 million thou-and cubic feet of gas produced in London, I find that to produce the same amount of light by electricity 350,000 tons of zinc

\* Care must be taken that the sulphate copper solution is absolutely saturated with the salt.

would have to be oxidised per annum in a primary battery. If iron were used the amount would be about 600,000 tons per annum, which is less than 10 per cent. of the annual production of iron in Great Britain (now amounting to say 7,000,000 tons per annum, the production of iron in the whole world being about 14,000,000 tons per annum). If sulphate copper be used in a primary battery it is not necessary to consider the annual production of the metal, as it could be almost entirely recoverable, giving reduced copper of the same character as is at present produced to the extent of 14,000 tons per annum in Great Britain, by the wet processes of Henderson and others.

It is also obvious that the hydrochloric acid solution of copper produced by the Henderson process, yields when precipitated by iron a vast amount of energy which is at present wasted in the form of heat. By a suitable arrangement of precipitate vats this energy may be utilised in the form of an electric current. If it could be all utilised, the precipitate of 14,000 tons of copper per annum would yield electricity sufficient to work 60,000 Swan or Edison electric lamps, but owing to the distance of many of the works from large centres of population, only a small portion of the waste energy can be utilised.

Mr. COLEMAN exhibited twelve cells in working order, and in answer to questions, said:—The iron plates are immersed in the solution of ferrous sulphate only, and do not dip into the solution of cupric sulphate, hanging about 3in. above its level. The latter solution is always in a state of saturation, for as metallic copper is precipitated the sulphuric acid liberated combines with the iron of the plates. The cupric sulphate solution is replenished from time to time through a funnel tube passing nearly to the bottom of the cell. The cells should be square, as with such a form, the iron plates can be increased in number.

## ON THE TREATMENT OF PYROLIGNEOUS DISTILLATE.

BY THOMAS MORGAN, M.L.M.E.

*University College, Bristol.*

IN the issue of this Society's Journal for May last, there appears, at page 19, an interesting and instructive paper by Mr. C. A. Fawsitt on “Wood Naphtha,” the said paper referring to, among other things, the plant suitable for producing crude pyroigneous liquors, and the method followed in West Scotland for deriving miscible wood spirit from them.

There is, in the aggregate, an extensive business in wood distilling carried on in the West of England and South Wales, and upon this ground I decided to attempt to follow Mr. Fawsitt's good example, and to supplement his paper by bringing before the notice of our new section of the Society an account of the methods generally adopted in this district for dealing with pyroigneous distillate, including also some particulars of the application at one place of a simple form of Coffey's still for the concentration of dilute naphtha wash.

In the district under notice, pyroigneous liquors are devoted to the manufacture of white (or gray) and brown lime acetates, white and brown lead acetates, crude and purified soda acetates, and both miscible and solvent wood naphtha. Culinary acetic acid is made at at least two works in the principality.

Carbonising retorts are here more generally known as ovens, and the carbonising process as stewing.

For all purposes it is found best to let the crude oven liquors have perfect repose for at least 24 hours before further dealing with them. If after the first period of repose they are drawn off from the deposited tarry oils, and then thoroughly agitated in another tank, and left for a further period of repose, so much the better. More tarry matters separate by gravitation.

For both brown sugar of lead and white or grey lime acetate the liquor is transferred from the reposing tank to a still, and then first the spirit and next the acid worked off into separate receivers. Copper stills are sometimes used for this process, and are heated either by direct contact of hot gases brought from an adjacent fire, or by means of an internal coil supplied with steam of from 20lb. to 30lb. gauge pressure, the corresponding range of coil temperature being thus from 225° to 250° Fahrenheit.

Cast-iron stills having either flat, hemispherical, or conoidal bottoms, and heated around the sides only by means of a wheel draft from a side fire, are in more general use for this process, but the coil-heated copper stills give, as might be expected, the best result as regards purity in the acid worked over, with, however, a corresponding slight diminution in quantity. The tarry residue in all these stills requires to be run out hot. In the case of coil-heated stills this requires to be done after every charge. Where fire-heated cast-iron stills are used, the residue is generally allowed to accumulate until a depth of about 2ft. of tarry matter exists in them. The stills are so proportioned for their charge that this shall occur at about fortnightly intervals. During an interval, 11 or 12 charges (one per day) are worked off, and at the end of the fortnight, after the acid from the last charge has been worked over, a higher heat is applied, and the tarry residue distilled until it attains a pitchy consistence on cooling. This condition is determined by withdrawing a portion from time to time on a rod passed down into it

through a stopper hole in the still cover. When the residue is sufficiently concentrated it is tapped out through the bottom, and either used in admixture with coal as fuel or sold as pitch.

When used for making brown lead-salt, the distilled acid is warmed (generally in a fire-heated pan) before litharge is added. The latter is thrown in in limited quantities, and while it is dissolving the liquor is vigorously stirred to keep the oxide off the bottom and hasten its solution. Scum and tar are carefully skimmed off as they rise. As saturation proceeds the temperature of the bath is increased by urging the fire. As soon as neutralisation is effected the liquor is syphoned off to concentrating pans, the fire under the mixing pan being damped down meanwhile. As soon as the liquor becomes syphoned off sufficiently low the bottoms in the mixing pan are ladled out and washed with strong distilled acid to exhaust them of any free litharge present. Evaporation of the liquor syphoned off is effected by means of steam coils laid in the pans. The liquor is concentrated up to caking density and is then ladled out into moulds for solidifying.

When devoted to the manufacture of white or grey limesalt the distilled acid is neutralised while cold, the temperature, however, rising spontaneously during the process. Prolonged stirring brings up tarry matter which is skimmed off. The "killed" liquor is next allowed to repose for 20 or 24 hours, and is then transferred to one or more fire-heated evaporating pans and carefully boiled down to nearly dryness. All tarry matter that rises to the surface of the liquor until the limesalt begins to "thicken out" is carefully skimmed off.

No mother liquor is separated in either the foregoing lead or limesalt process.

The above method of producing "distilled" (or white or grey) limesalt differs slightly from that described by Mr. Fawsitt (*Journal*, p. 320, 1st paragraph) in one respect—namely, that in Scotland the spirit and acid distillates from the pyroligneous liquor are not kept separate, but instead are together treated with lime and then the spirit is distilled off to make it into a miscible product. By this method of neutralising the lime deprives the spirit of some of its tarry oils, which to that extent may be expected to deepen the colour of the residual limesalt.

In our district the spirit obtained by the foregoing process is almost invariably marketed as *solvent* naphtha. This is not usually sold subject to any minimum limit of strength, but it must be nearly water white and keep its colour tolerably well while in druggists' stock.

It is more in request than miscible naphtha amongst varnishers and polishers for some purposes. The price it commands generally approximates to about three-fourths of that of miscible. It is prepared by simple concentration in copper stills heated by either steam coils or jackets, the first naphtha still, however, being sometimes worked over hot gases brought from a firegrate outside of the still-room. At some works nothing whatever is put into the stills with the charge. At other places a limited quantity of slaked lime is added to the charge for one or two of the rectifying operations, but sometimes in the last one only. Solvent naphtha customarily gets one distillation less than miscible, and is consequently not so strong. When finished the strength registers from 35° to 50° over proof, but owing to the increase of density from oils in solution it contains more spirits than so shown, especially in the case of the lower strengths.

From what has been said, it is clear that commercial solvent naphthas must be variable in composition. The yield of solvent is considerably in excess of that of miscible, and this in part compensates for the lower

price obtained for it; but it would, in my opinion, have been generally more profitable in the past to have strongly limed it while weak and then worked it forward for miscible. Commercial solvent is often limed and re-distilled by methylators when the difference between the prices of the two descriptions affords a profit on the operation or when miscible is scarce.

Manufacturers who followed the white limesalt and solvent naphtha process used to be further remunerated by obtaining from 5d. to 9d. more per unit per cent. of acetate of lime in their limesalt than could be obtained per similar unit in brown limesalt. Of late years consumers have not been willing to pay so large a difference for the purer salt, and consequently its manufacture, as well as that of solvent naphtha, has fallen off. It may be expected that the increasing scarcity of the latter will enhance its price.

In our district the method which produces brown acetate of lime and miscible naphtha is most generally followed.

For this process the pyroligneous liquors are after a period of repose decanted, and then neutralised with slaked lime as the first step. Whether in respect of both quality and quantity of lime salt and naphtha the liquor ought to be accurately neutralised, or else either under-limed or over-limed, much difference of opinion exists. Whichever may be the practice followed in this respect, it is of importance that plenty of time and labour should be bestowed upon the operation. Prolonged agitation and careful skimming-off of the tarry matters thrown up will much improve the quality and appearance of the limesalt. Litmus paper is sometimes used as an indicator, but more generally the changes in colour, taste, and smell of the liquor, as well as some frothing and weak effervescence, are relied upon to notify the degree of saturation. Naturally the purer the lime used for neutralising the less will be the quantity of undissolved sediment (from some limes granular, from others slimy), and correspondingly one source of loss from imperfect drainage and washing will be minimised.

After settlement the clear limed liquor is transferred to the first still—in some places designated the wash boiler, and at others No. 1 still. It usually consists of some form of wrought-iron boiler, and is heated directly from a fire beneath. Occasionally internal steam coils are used, the object being to prevent the formation of hard deposit difficult to remove, which sometimes occurs on bottoms over fires.

Distillation is continued until all the naphtha has passed over. Roughly the quantity of this distillate amounts to from 20 to 25 gallons per ton, or per 100 cubic feet of cordwood retorted. One means of determining whether all the naphtha has come over is that of casting a small portion of the latest runnings over a shovelful of white hot fuel, clear of smoke, and carried to a dark corner. If there is no flash of flame then it is assumed that all the spirit has been driven over. This rough-and-ready test, in universal use, Mr. Fawsitt justly condemns. Another test is that of density, but this is not more trustworthy than the flash test, because owing to oils in solution naphtha in quantity worth recovering may be present when the density registers 1·000. Naturally stillmen are averse to having much liquor of such a density worked over, nevertheless to err from excess rather than defect in this direction is better for the proprietor's interest. Any crude spirits that fail to be driven over in this operation become lost. Every wash boiler has a habitude of its own that needs to be taken into account. For instance, I at one time had to do with one heated by a fire underneath, whose initial rate of delivery was usually from 10 to 11

gallons per hour, at a strength of from 65° to 70° under proof—but both strength and quantity varying in part with the strength of the charge. Four hours after starting to run, and with the fire kept as near as might be of the same intensity, the delivery would have fallen off to perhaps 7 or 8 gallons per hour, and the strength to 80°—more or less—under proof. If later on, when 3 or 4 gallons of distillate per hour was coming off at say 90° under proof, the fire was checked (either by lowering damper or slightly opening the fire-door) so as to appreciably diminish the quantity coming over, then the strength would go up to say 87° under proof. And later still, towards the end of the operation, when only a fine wire stream was running, that would register 100° under proof. If then the fire was checked to reduce the delivery to a dribble the strength would go up to 99° or 98° under proof. This arose from the large amount of unclothed upper surface exposed by this still, which was a wagon boiler that at one time had been employed for steam generation. The large amount of cooling surface fractionated the vapours inside by condensation—a process which I suppose might be called dephlegmation. The best results were not to be got from this still by clothing the exposed surface (for this means lowered the mean strength of the distillate, or in other words, increased its quantity), but by long and slow working when the distillate was getting weak.

Instances are, however, to be found where too large a proportion of cooling to heating surface obtains in the wash boiler. I have met with such a case at each of two different works, and in both cases the yield of naphtha was unsatisfactory.

The residue in the wash boiler, after removal of the naphtha, is run out into evaporating pans (generally of wrought iron) and boiled down nearly to dryness. The limesalt is lifted out to strainers, and after from twelve to twenty hours' draining (the longer the better) it is next spread over a drying floor, which in most cases is formed over the carbonising ovens.

Except a small and constant quantity of liquor left on the bottom of the pans each day all the rest is thickened out, and thus no mothers have to be dealt with.

The wash boiler is cleaned out either weekly or fortnightly, preferably the former. In fire-heated wash boilers towards the end of each operation some tarry oils come over which float in spots on the surface of the distillate. Pungent incondensable vapours, of disagreeable smell, come off earlier in the process and continue to the end. Both of these increase as the sediment accumulates within the boiler. Cleaning is more easily effected when underliming of the oven liquor is practised. When, however, the boiler is wrought iron the rivet heads in time become corroded from underliming and leaks are set up. Overlimed liquor is apt to deposit tough sediment in this still, and also to prime over into the condenser. The residue when run out from the still to the boiling-down pans is also liable to froth up and boil over during evaporation.

At some works the limed pyroliguous liquor is run direct into hemispherical or saucer-bottomed cast-iron evaporating pans, to which movable cast-iron covers are applied after charging, and next a connection is made from a hole in each cover to a condenser by means of a portable pipe. The naphtha wash is first distilled off from each pan and then the cover is removed and the remaining liquor boiled down to nearly dryness. Next the limesalt is taken up, drained and kiln dried. By this method of boiling down the sediment usually intercepted in the wash boiler (as before mentioned) becomes incorporated with the brown limesalt and to that extent deteriorates it.

At this point I may make reference to the value of hot limesalt liquor, as it leaves the wash boiler, for cleansing the condensing pipes connected with the carbonising retorts. Usually these are cleaned out at from monthly to four-monthly intervals, as may be deemed necessary. At some works cleaning is, where practicable, done by means of scrapers. Where bends interfere with scraping the condensing tanks are sometimes drained of water, and either the pipes disconnected or else heat from cages of fire radiated on to them to melt out their internal coating. If instead of these means the pipes are filled up for a couple of hours with brown limesalt liquor charged hot the deposit within them becomes very completely removed. Naturally there is a better result when the outside condensing water has been previously drained off, but in cases where this cannot be done a second charge of hot liquor perfects the cleansing of the pipes.

I may also mention here that a small proportion of this limesalt liquor added to common alluvial clay makes a first-class lute and lute-washing for the retort doors. This addition, besides increasing the adhesiveness of clay lutes generally, also entirely prevents the cracking which is apt to occur in them while drying. The same luting is also excellent for still covers.

The weak naphtha distillate from the wash boiler or No. 1 still is mostly concentrated by passing through a series of stills, generally four in number, of diminishing capacity. Sometimes all these are of copper, but generally the first one, and sometimes the second, is of either cast or wrought iron. Some people hold that copper condensing pipes are indispensable for this series. Others use iron, lead, and copper in succession, the copper being connected with the finishing still. I have seen unsurpassed miscible naphtha made year after year by means of iron condensers for the first stills and lead ones for the last two. On the whole, copper condensers are preferable, and, in these last days at least, the price of the metal is no impediment to its adoption.

Where over-liming of the crude oven liquor is practised, ammonia comes forward with the naphtha distillate from all the stills. In such circumstances the first stills wear very well when of wrought iron. Generally the ammonia is intercepted in the finishing still. This is done by adding oil of vitriol to the charge—a proportion of about one or one and a quarter pints per 100gal. of spirits of 55° over proof being generally sufficient to redden test paper. I am not aware that it is ever attempted to recover the ammonium sulphate from the still residue. It would hardly pay for being done.

When under-liming is practised, the ammonia goes forward with the lime-salt to the kiln, and thence to market, if it survives the kiln. It is sometimes alleged that the odour of under-limed lime-salt is more agreeable than that of over-limed, and also that it keeps crisper and drier in stock.

Whether more tarry matters come forward or not in the distillate from the wash boiler when underlimed liquor is treated, is a point upon which wood distillers are not agreed. The measure of fouling of the succeeding stills might be expected to decide the matter. From never having had to do with a plant consisting of a cast-iron wash boiler, and copper concentrating stills throughout, I myself have not had sufficient experience of under-liming to enable me to offer an opinion, but I have been assured that when under-liming is practised, the tarry and colouring matters in the residues of Nos. 2 and 3 stills (the wash boiler counting as No. 1), will run away and leave a clean still if tapped off hot, and for this reason only a small quantity of slaked lime, if any, is added with

the charges to those stills to prevent adhesion of a deposit. It is also stated that only a little lime is required in the succeeding stills for discolouring their distillates, and that naphtha so produced is perfectly miscible, of good smell and retentive of its water-white colour. In the absence of ammonia, from pursuing this method, no acid is used in the finishing still. Doubtless the lime used in this process is sufficient to decompose any acetate of methyl brought forward in the wash boiler distillate from under-limed liquor.

When the oven liquor is slightly super-saturated with lime, the wash boiler distillate from it can, in the next concentration, be worked without any addition of lime to the charge, but the residue must be tapped off warm. This system obviates the necessity of frequent cleansing of the still, which sometimes has projecting rivet heads over the bottom inside, or else a heating coil close to the bottom—either being an impediment to cleaning out.

But in the next operation lime must be used, otherwise a tarry coating will be deposited that will not run off, even if the residue be tapped out at full heat, nor can it be removed by scraping after the still is cold.

This still, if a jacketed one, must be kept clean, otherwise it will not exhaust its charge to a sufficient extent. The strength of its charge will register perhaps from 5 to 10 degrees under proof. The addition of from 15 to 20 lb. of slaked lime per 100 gal. of such a charge will prevent any adhesion of deposit on the still bottom, and enable the sediment to be easily swilled out with the residual liquor and leave a bright still. It is better to strew in the lime in the form of dry powder than to add it in wet clots. The latter disintegrate with difficulty even under prolonged stirring.

For the succeeding operation, about one-third of the foregoing proportion of lime may be sufficient to add for keeping a clean still. The distillate from this last-mentioned operation is usually almost wholly freed from colouring matter, and it only remains to make the final concentration and remove the ammonia to produce a spirit of good smell, permanently colourless, and perfectly fit for the market.

I have next to notice the application for the rectification of wood naphtha of a still on the principle of Coffey's. I am not aware that this still has been so employed outside of this district. It was adopted in the Forest of Dean, in 1870, at the instance of the late Mr. Ernest T. Chapman, F.C.S., who at that date was connected with the erection of a wood distillery there. The still was intended to deal at first hand with neutralised oven liquor, and to concentrate it up to 40° or even 60° over-proof in one operation, and thus as a substitute for the No. 1 or wash still to supersede the use of at least two succeeding stills in the ordinary suite.

Two Coffey stills—locally designated plate stills—were erected, but when they were put to work it was found that although they would concentrate up to 60° over proof in one operation, the quantity of weak liquor they were capable of dealing with was surprisingly less than had been expected; and further that owing to solid matter held in suspension in the neutralised liquor (even after 24 hours' standing), and also the tarry matters present, deposition of solid matters occurred to such an extent in the upper parts of the stills as to choke them up after a few days' working. In consequence of this unlooked for result, a wash boiler was erected, and the plate stills were applied to dealing with its distillate. For this duty they ultimately gave satisfaction, but not until a long period had been spent in finding out the best way of dealing with them, several alterations having also to be made both in them and their adjuncts.

Later on it was deemed to be in one respect safer to take off their distillate at from 10° to 20° over proof rather than to concentrate it to a higher strength, because, owing to the circumstance that on three different occasions excise officers in London had refused to pass their produce for methylation, upon the ground that it was too pure in quality and deficient in smell, it was concluded that (1) the greater amount of re-distillation effected within the stills tended to over-purify the product, and (2) that the lower temperature prevailing in the upper parts of the stills, when high concentration was going on, disabled some of the usual strong-smelling bodies from vaporising and going forward with the naphtha spirit. The purifying tendency in this case seemed to be almost identical with the action of stills of similar principle devoted to the production of "silent" ethyl alcohol.

Since the time when it was concluded the plate stills were liable to make the naphtha too good, the proportion of concentration effected in them has ranged from about  $4\frac{1}{2}$  to 1 to  $5\frac{1}{2}$  to 1 by volume:—thus 1 gallon of 10° over proof has been collected from each  $4\frac{1}{2}$  gallons of wash, registering by hydrometer 83° under proof (but being actually about 77° under proof) entering the still; and one gallon of spirit 177° over proof has been separated from each  $5\frac{1}{2}$  gallons of wash of 863° under proof by hydrometer test entering the still—the wash being, however, actually not weaker than 773° under proof, as proved by the amount of spirit collected. The former example is an average of the work done by a still composed of a pile of 22 trays or plates, each plate being a flat rectangle 3 ft. long by 1 ft. wide in the clear inside of a flange  $1\frac{1}{2}$  in. high, which stands up vertically all around the margin of the plate. The plates are of cast iron,  $\frac{3}{4}$  in. thick throughout, and are 3 ft. 1 in. long by 1 ft. 1 in. wide by 2 in. deep externally. The flanges are planed true on their upper edge, and, similarly, anarris about 1 in. wide is planed all around the margin of the outer side of the bottom. Thus the even top edge of the lowest plate in the pile is borne upon by the even margin of the bottom of the next plate above, and so on upwards—the top tray being covered by a plain flat plate. Two or three coils of fine soft twine are laid around on the top edge of each flange, and painted over with thin white-lead putty to form a joint with the bottom of the next plate. The whole pile is cramped together by means of vertical bolts outside. Near one end of each plate (except the lowest one) three holes exist in the bottom—the two side ones being appointed for letting liquor pass through downwards, and the middle one for letting vapour pass upwards. A little fillet or flange, standing  $\frac{1}{2}$  in. high, surrounds each of the liquor holes, and these flanges keep the plate covered with a stratum of liquor  $\frac{1}{2}$  in. deep. The flange surrounding the middle hole is 1 in. high, and as, therefore, no liquor can overflow to descend through it, it is kept clear for the ascent of steam and spirit vapours. In building the still the second plate laid will be the first having holes in its bottom. The third plate is laid with its holes "end for end" with those in the second one, and succeeding plates are so reversed in succession to the top.

A regular stream of weak naphtha wash being supplied to one end of the top tray flows over it to the other end and flows down to the next plate below. It then traverses this plate to the opposite end and falls through to the next below, and so on to and fro to the bottom—each plate meanwhile being covered with a layer of liquor half an inch deep. Steam of from 5 lb. to 20 lb. gauge pressure enters at one end of the bottom plate through a  $\frac{1}{2}$  in. pipe, the supply being regulated by a stop valve. The steam travels up-

wards through plate after plate and traverses the surface of the liquor in a direction contrary to the flow of the latter. The steam keeps the liquor on several of the lower plates at boiling point and completely deprives it of all naphtha. At some point higher up all the steam becomes condensed except such as goes forward in connection with naphtha vapours, and at a temperature below 212° F. Above the horizon of complete steam condensation the temperature within the still goes on decreasing, and while the supply of wash and steam must be mutually regulated so that all the spirit shall be separated from the former the supply of both must be restricted so that the temperature within the upper trays shall not exceed a certain limit, which varies with the strength of both the distillate collected and wash supplied, and, slightly, from other circumstances. The temperature at the top of the still can, of course, be ascertained by means of a thermometer, but generally the stillman obtains sufficient information from lightly feeling the plates with the palm of his hand. Seldom is there any variation for hours together, but when there is he directs his attention to the wash supply and the pressure (for temperature) of the steam supply.

The boiling spent wash escapes from the bottom plate through a vertical U tube about 3ft. deep. This tube provides about 1½lb. per square inch of back pressure to prevent the entering steam from escaping by a short cut through the wash exit pipe, and at the same time constitutes a safety outlet in the event of any accidental choking of the exit-pipes above. Of course while all is clear above there can be no appreciable pressure within the still. The naphtha picked up by the ascending steam and vapours passes out from the top plate through a pipe to a worm within a cast-iron condensing tub, supported at a point a little higher than the still top. Within this worm the more watery portion of the naphtha vapour is condensed and flows back direct to the top tray of the still. The uncondensed vapour from the first worm passes on through a second worm and tub wherein a further portion is condensed and returned to the top of the still. In the early history of these stills, while a stronger distillate was being produced, the condensation from a third worm and tub was also conveyed to the top tray of the still, but now all that condenses beyond the second tub is retained outside of the still. The wash supplied to the still passes first through the worm tubs and constitutes their condensing medium. Its temperature is increased in each succeeding tub, and it enters the still more or less hot.

No attempt has been made to utilise the heat carried off by the spent wash at boiling temperature. Some heat is also lost by radiation from the surface of the stills. They have never been clothed, because it was thought desirable to have the tray joints always available to inspection. Roughly, one of these stills with condensing tubs exposes about 40 superficial feet of surface, and may be expected to lose heat equivalent to the condensation of say 10lb. of steam (equal to one gallon of condensed water to the escaping wash) per hour. Much of the heat passing from the still in the naphtha vapours is captured by the wash passing through the condensing tubs and carried back to the still therewith. By deducting the quantity of wash entering the still from the sum of the quantities of spent wash and strong distillate escaping from the still the quantity of steam expended for working the still may be ascertained.

The wash supplied to these stills usually ranges from 80° to 90° under proof by Sikes's hydrometer, but for the reason before stated the wash is always

richer in spirit than its density referred to Sikes's tables indicates. As before mentioned, the first-stated example of concentration from 83° under proof to 108° over proof was taken from a still of twenty-two trays. At 3 feet per tray this still provided 66 superficial feet of liquor surface for direct contact with the steam and hot vapours. The supply of wash was at the rate of 1358 gallons per hour, and the yield of distillate 285 gallons per hour. The second example (86°38' under proof wash concentrated to 177° over proof product) was from a still of twenty-seven trays, which thus provided 81 superficial feet of liquor surface for contact with steam and vapour. These examples show that for a concentration of dilute liquors of the strength stated to about one-fifth of their volume approximately 5 superficial feet of plate surface per gallon of wash supplied per hour is necessary.

By the time that from 5500 to 6500 gallons of wash has passed through one of these stills, so much deposit has generally accumulated within it—chiefly in the upper part—as to interfere with the passage of liquor and vapours. The trays have then to be cleaned. Convenient facilities for effecting this were not provided in the stills under notice, and consequently they have to be taken apart for the purpose.

As soon as a stillman has learnt to adjust the supply of wash and steam to these stills they afterwards give him very little trouble. They run for hours without requiring more than the most trifling attention.

An ordinary No. 2 still does not operate upon more than 150 gallons of wash-boiler distillate per operation. To get 6000 gallons through such a still it would have to be charged, luted down, worked off and run out 40 times, and portions of the distillate from each operation would have to be caught according to strength in separate vessels, and a portion of it repassed through the same still. Furthermore the average strength of the first portion of the distillate kept separate for treatment in the succeeding still would certainly be something below proof in strength. From these points I think it will be seen that the method of distillation in plate stills just described is an improvement upon that which commonly obtains for weak naphtha liquors.

I will next make reference to the yield of some of the products from wood distillation. Assuming an ample and efficient condensing apparatus for dealing with the vapours from the carbonising ovens, then the quantity and strength of the pyroigneous distillate obtained most largely depends upon the amount of non-constituent water resident in the wood treated, and next upon the temperature of carbonisation.

It being in this district most customary both to buy wood and sell charcoal by bulk instead of weight, we are accustomed when speaking of yields to refer to our "cord" of wood as the unit for comparison. Our cordwood is (or ought to be) cut to a length of 2ft. 2in. and the ordinary standard cord consists of a rank of such sticks piled transversely to a height of 2ft. 2in. Thus the volume of a cord is 78½ cubic feet nearly, and when composed of bark-stripped coppice oak of about 14 years' growth weighs from 14cwt. to 16cwt. The coppice oak just mentioned can often be obtained in large quantities, and gives as good yields as any other description of wood that can be obtained in similar quantities.

Assuming that a cord of coppice oak weighs 15cwt. when well air-dried, and that a bushel of charcoal from it weighs 13½lb., then good working yields in this district per 100 parts by weight of such wood are as follow:—

Liquid Distillate (tar, crude acid, crude naphtha, etc.	Acetic Acid (glacial).	Naphtha, density 8263.	Charcoal.
50 to 60	3.44	1.03	31.25

If the cord be taken to weigh 16cwt. then the foregoing figures representing yields must be abated one-sixteenth. The density of the crude acid and spirit liquor varies from 4° to 3½° Twaddell. It may be noticed that our yield of acetic acid is much under that realised in Scotland as stated by Mr. Fawsitt. He did not state their yield of naphtha.

Notwithstanding there are so many encyclopaedical treatises and monographs on wood distilling, none of them, so far as I am aware, give analyses of either brown sugar of lead, white or grey limesalt, or solvent and miscible naphthas. We are now indebted to Mr. Fawsitt for an analysis of miscible naphtha. The following analysis of presumably brown limesalt appears at page 2 of Thomson's Dictionary:—

* Acetic acid.....	48.22	54.02
Lime .....	35.00	
Carbonate of Lime .....	8.17	
Tarry matter .....	2.99	
Water .....	5.62	
	100.00	

The proportion of tarry matter appears to be low and of water high. It may also be remarked that the acetic acid requires for its saturation only 26.47 units out of the 35.00 of lime present, leaving an excess of 8.53 per cent. of lime present in the salt. Some of this is perhaps engaged with the tarry matter. On the whole this seems to be a very highly limed sample, and remembering that the crude acid is neutralised with slaked caustic lime, how is it that carbonate of lime appears in this salt?

Brown limesalt is usually sold guaranteed to contain 70 per cent. of anhydrous lime acetate. Much that is delivered contains from 72 to 75 per cent.

Before concluding I would like to make brief reference to the custom of selling miscible naphtha by tests referring to Sikes's hydrometer tables—a practice that Mr. Fawsitt does not entirely approve of. In one respect, however—namely, that of ascertaining the amount of water present in miscible naphtha, it would seem from Mr. Fawsitt's determinations, that Sikes's tables are fairly accurate, as the following examples will show:—

Miscible naphtha of 820 density Mr. Fawsitt shows contains 12 per cent. of water. By Sikes's tables hydrated alcohol of the same density (60° over proof) contains (proof spirit to consist of 4.33 per cent. of absolute alcohol and 50.7 per cent. of water by weight) 12.49 per cent. of water. By the table in Fownes' Chemistry alcohol of the same density contains 12.42 per cent. of water. Next from Messrs. Dittmar and Fawsitt's determination of the naphtha in wood spirit of 815 density it contains by inference 7 per cent. of water. By Sikes's tables common alcohol of the same density (67° over proof) contains 7.15 per cent. of water, and by Fownes' table 7.33 per cent. of water.

I have not met with any explanation why the zero of Sikes's hydrometer was placed so high as 815 at 60° Fahr. By the tables it will be seen that at 47° Fahr. this density represents 70° over proof, containing by computation 4.93 per cent. of water. In the tables for still lower temperatures the strength corresponding to zero is not given; in fact, nowhere is a higher strength than 70° over proof specified, and this circumstance has led many (myself included at one time) to suppose that 70° over proof represented absolute alcohol.

Taking it as before, that proof spirit contains 4.93 per cent. of alcohol; and, further, that alcohol at 60° Fahr. has a density of 7938, then for Sikes's tables absolute alcohol would be represented by 75.1° over proof.

In working wood naphtha through the finishing still the first and strongest runnings rarely exceed 65°

or 66° over proof. The highest I have met with was 68.7° over proof.

During the discussion a member, referring to the analysis of brown limesalt set before the meeting, suggested that the presence of carbonate of lime arose in this way: An excess of caustic lime was used for neutralising, and some of this became carbonated later on while in the drying kiln.

## Obituary.

### ALFRED TRIBE, F.C.S.,

LATE LECTURER IN CHEMISTRY AT DULWICH COLLEGE, ETC.

ALFRED TRIBE, whose name has become well known both in this country and in Germany, through his physico-chemical researches in conjunction with Dr. Gladstone, F.R.S., was born in the year 1839, in the neighbourhood of Oxford Street, London. He spent the first years of early childhood at Bradford-on-Avon. Returning to London when six years old, his education was carried on there, and as a boy he attended the Royal College of Chemistry in Hanover Square. Here he acquired a knowledge of chemistry, and received encouragement from Prof. A. W. Hofmann. In 1855 he became assistant to Dr. Medlock, subsequently to Dr. Forbes Watson, who had a laboratory in Archer Street, Westbourne Grove, and more recently to Prof. Williamson and Dr. Bernays. In 1862 Mr. Tribe went to Heidelberg and studied under Busch; in 1863 he returned to St. Thomas's Hospital. He became in 1865 private assistant to Dr. Gladstone, and in 1877 was appointed lecturer on Metallurgy at the National Dental Hospital. As lecturer on Theoretical and Practical Chemistry at Dulwich College, for which appointment he was chosen in 1874, he continued up to the time of his death, retaining also the two other appointments at the Dental Hospital, and under Dr. Gladstone. The principal papers communicated by him were on "The Freezing of Water and Bismuth," *J. Chem. Soc.*, 1868; "A Specific Gravity Bottle for Spontaneously Inflammable Liquids," *Phil. Mag.*, 1873; "The Agglomeration of finely divided Metals by Hydrogen," *J. Chem. Soc.*, 1874; "Experimental Contributions to the Theory of Electrolysis," *Proc. Roy. Soc.*, 1876 and 1877. In conjunction with Dr. Gladstone he published a number of papers, the principal of which are entitled, "A law in Chemical Dynamics," *Proc. Roy. Soc.*, 1871; "An Air Battery," *Proc. Roy. Soc.*, 1873; "Researches on the Action of the Copper Zinc Couple on Organic Bodies," in 10 parts, *J. Chem. Soc.*, 1873 and 1885; "Various papers on the Copper Zinc Couple, and its preparation," *Proc. Roy. Soc.*, 1872, and *J. Chem. Soc.*, 1873 and 1879; "A series of papers on the Joint Action of Aluminium and Iodine on the Alcohols and Ethers," *J. Chem. Soc.*, 1876 and 1885; "Investigations into the Action of Substances in the Nascent and Occluded Condition," *J. Chem. Soc.*, 1879. In 1883 he published, in conjunction with Mr. Gladstone, a small treatise in the Nature series of Messrs. Macmillan,

\* 48.22 C<sub>2</sub>H<sub>4</sub>O<sub>2</sub> or C<sub>2</sub>H<sub>3</sub>O<sub>2</sub>

 2.50 + 9.4 CaO with (em. acid?)

entitled "The Chemistry of the Secondary Batteries of Plante and Faure." Mr. Tribe took out some patents in connection with the secondary batteries; in these Dr. Gladstone had no interest. In 1866 Mr. Alfred Tribe was married. He has had a large family, and now besides Mrs. Tribe, a son 16 years of age and three very young children remain. His death took place on November 26th, 1885.

## Journal and Patent Literature.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*Improvements in Machines or Apparatus for the Manufacture of Ice.* H. H. Lake. From Wm. Kaydt, Hanover, Germany. Eng. Pat. 15,475, November 24, 1884.

THIS invention relates to apparatus for the production of cold and the manufacture of ice, by means of the use of carbonic acid instead of liquids such as ether, ammonia, or sulphuric acid, carbonic acid having the advantage of being cheaper than the other fluids, besides being capable of producing greater cold. Thus a much smaller compression pump can be used than with other liquids; for instance, only about one-sixth of the size of that required for ammonia. On the other hand, carbonic acid must be worked under much higher pressures (from 30 to 75 atmospheres), and therefore it requires a compression pump of special construction. Several designs of pumps are given in the specification, of which the

liquid through the plunger, by means of the tubes  $x$ ,  $y$  and  $u$ , shown in the drawing.—B.

*Improvements in Filters, and in Arrangements for Filtering.* W. Oldham, Manchester. Eng. Pat. 16,326, December 12, 1884.

THIS invention relates principally to improvements in the application of the filters described in the Patent 7831, 1884, and to means for connecting a number of them to act together, and for cleaning, removing or replacing them.—B.

*Improvements in Apparatus for Separating Solid Impurities from Water or other Liquid.* A. Howatson, London. Eng. Pat. 16,706, December 19, 1884.

THE inventor constructs apparatus for depositing and removing solid impurities contained in water or other liquids, by arranging in a vessel of any convenient shape a number of superimposed trays or plates, each tray having a number of wells or recesses with inclined sides, and terminating below in small openings. All these openings of the wells of each tray are connected by one or more closed channels or tubes, which are carried through the sides of the containing vessel to a common discharge pipe. The impure water or liquid enters the vessel from below, and traverses upwards in a serpentine path over each successive tray, allowing the impurities to settle and slide down the inclined sides of the wells. Here they collect in the small channels, whence they are drawn off at intervals. The cleared liquid leaves the vessel at the upper end.—B.

*Improvements in Filter Presses.* J. H. Johnson. From F. and R. Quarez, Paris. Eng. Pat. 2642, February 20, 1885.

THE improvement in filter presses contemplated by this invention refers to the mechanism for applying the pres-

surement represents one. The principal considerations in the construction of the pump, are the necessities of keeping it cool, and of preventing the escape of the acid through the stuffing box. For the latter purpose the inventor provides the gland with a circular chamber  $a$ , into which any acid escaping from the stuffing box  $s$  is carried, and led by means of the pipe  $b$  to a small gasholder, from which it is returned to the pump either by suction or by injection. The chamber  $o$  is also connected through the tube  $g$  with an oil reservoir, by means of which the stuffing box  $s$  is kept properly lubricated, whilst any escape of either oil or acid is prevented and cut off by the auxiliary gland  $t$ . The pump is surrounded by liquid in the cistern  $z$ , for the purpose of cooling, which is further aided by the circulation of a cold

sure, and to the passages which carry the liquid through the press plates. The improvement in the pressure mechanism enables an additional and adjustable pressure to be applied, after the nuts of the two main bolts, which hold the plates together, have been screwed home. The press plates consist of alternate "water plates" and "juice plate," and the improvement refers to passages left through the plates, and which are arranged to allow for the proper circulation of the washing or displacing liquid, with the view to force out the juices of the materials under treatment, in the order of their density, the object being to extract the denser parts of the juices before they shall have had time to become diluted by the displacing liquid. There are devices for regulating the admission or reversing the course of the liquid, if necessary, which

are indicated in the sheet of drawings accompanying the specification.—B.

*Improvements in Thermostats.* W. E. Gedge, From H. F. Perry, San Francisco. Eng. Pat. 10,049, August 25, 1885.

THE invention consists of a closed air-tight chamber, inserted into the room or space to be heated, and subjected to the same degree of heat. The chamber is in connection, by means of a tube, with a floating bell or air-holder, which is raised or lowered simultaneously with the expansion or contraction of the air in the closed chamber, according as the temperature rises or falls. The float acts upon a valve adjusting the admission of the air of combustion to the source of heat, thus regulating the heat of the room.—B.

*New Condensation Apparatus.* L. and C. Steinmüller. Ger. Pat. 31,238, September 13, 1884.

THE apparatus here figured is recommended for the condensation of the vapours of volatile liquids, as, for example, the benzine vapours from apparatus for the extraction of fat from bones. The vapours are led by the elbows *a* into thin-walled tubes *p*, or metal boxes. Each of the taps *e* supplies a separate division of *m* with water, which is thus distributed in jets over the

whole surface of the condenser system *p*. The condensed product runs away, as shown, into the water, and the two liquids pass out through *o* into the tank *R*, where they separate.—W. D. B.

## II.—FUEL, GAS, AND LIGHT.

*Improved Means of Utilising Waste or other Gaseous Products of Combustion.* E. Biedermann and E. W. Harvey, London. Eng. Pat. 15,127, August 17, 1885.

THE highly-heated gases escaping from regenerative gas furnaces are conducted through a chamber filled with fuel, which has been previously raised to incandescence by the admission of air in the ordinary way. The carbon dioxide of the waste gases takes up another atom of carbon, becoming converted into monoxide, and becoming again available for fuel.—A. R. D.

*Improvements in Carburetters.* J. H. Johnson, London. From E. F. Delanarc-Deboutville and L. P. C. Malandin, Fontaine-le-Bourg. Eng. Pat. 15,248, August 19, 1885.

THE carburettet chamber is filled with sponges or other porous material, and is supplied with liquid hydrocarbon from a reservoir above by a pipe provided with a suitable glass for observing the rate of drip, so that a constant level of liquid may be maintained in the chamber. The carburettet is to be worked in connection with a gas

engine, so that each stroke of the piston draws air through the chamber into the cylinder. The inlet and outlet from the carburettet are provided with suitable valves to prevent the return of flame from the engine or the escape of gas into the air.—A. R. D.

*Process for the Separation of Carbonic Oxide from the Products of Furnaces or Gas Producers.* A. R. Huntington, London. Eng. Pat. 15,310, August 20, 1885.

THE products of combustion are exposed to the absorbent action of a solution of cuprous chloride under the pressure of several atmospheres, the nitrogen being allowed to escape by a suitable valve. The carbonic oxide that has been absorbed is released by mechanical rarefaction, and collected as convenient. The cuprous chloride solution is preferably made by dissolving chloride of copper in solution of ammonium chloride.—A. R. D.

*Improvements in the Manufacture of Hydrogen.* R. Lehmann, London. From Jacob Oetli, of Cossonay, Switzerland. Eng. Pat. 16,759, September 4, 1885.

STEAM is passed through highly heated tubes of refractory earthenware, partly filled with iron filings,

and in which a partial vacuum has been previously produced. A certain proportion of hydrogen is added to the steam, and this, together with the action of the iron filings, tends to destroy the proportion between the oxygen and hydrogen formed by the decomposition of the steam, and to prevent them from re-uniting. This effect is promoted by the reduced pressure in the tubes, and by the loss of heat due to the splitting up of the aqueous vapour. From the tubes the gases pass through any convenient separators to gas-holders.—A. R. D.

*Improvements in Apparatus and Materials Employed in Producing Self-igniting Luminous Gas for Signalling Purposes.* W. R. Hodgkinson, London. Eng. Pat. 16,464, September 14, 1885.

THE self-igniting gas is produced by the decomposition of sodium phosphide on access of a suitable liquid. The volume of gas evolved is increased by the addition of an alloy of sodium with some less readily oxidisable metal. Magnesium silicide may be substituted for sodium phosphide. For particulars of the apparatus employed the specification and drawings must be consulted.—A. R. D.

*The Present Position and Prospects of the Processes for the Recovery of Tar and Ammonia from Blast Furnaces.* William Jones. Proc. Iron and Steel Institute Meeting in Glasgow, September, 1885.

"IN the West of Scotland there occur vast beds of coal, known as splint coal." This coal is admirably adapted

for blast-furnace purposes, giving a good, strong coke, capable of withstanding, in a high degree, the crushing effect of the ores, etc. Certain varieties of it agglomerate very little during coking, and do not decrepitate. The principal localities for furnace splint coal in the Clyde basin are: Bothwell and Hamilton district, Airdrie and Coatbridge, Quarter, Wishaw, Glasgow, Cambuslang, Rathfriland, Govan, etc.

Scotch splint coals contain on the average 40% of total volatile matter, of which 28 to 35 go to form tar, gas,

(I.) Methods depending on the condensation or cooling of the gas.

- (a) Alexander and McCosh process, or the Gartsherrie method.
- (b) Dempster process.
- (c) Henderson process.

(II.) Methods depending upon the use of acids, without the cooling of the gas.

- (a) Neilson process, or Summerlee method.

etc., and they yield on the average 50 to 55% of fixed carbon. Were the average amount of nitrogen in Scotch splint coal (1.35%) all evolved as ammonia, and obtained as sulphate of ammonium, this would amount to 142½ lb. of pure sulphate; but in blast-furnace practise only from 17 to 20% of the nitrogen contained in the coal is evolved as ammonia. The author considers the following method of deduction to give a very fair idea of the amount of sulphate of ammonia that may be obtained in practise on the large scale:—An average sample of the coal is tested for the amount of nitrogen it contains, the latter is calculated to ammonium sulphate, of which amount 16% is taken as the amount of pure sulphate that may be recovered. Taken as a whole, the gases from Scotch blast-furnaces have the following composition:—Carbonic oxide, 25 to 30; carbon dioxide, 3 to 8; hydrogen, 5 to 7; marsh gas, 2 to 4; nitrogen, 52 to 60% by volume. The temperature of the escaping gases varies from 400° to 650° F. (204½° to 343½° C.), and the volume of gas per ton of coal averages 125,000 cubic feet at 60° F. (15.5° C.). These 125,000 cubic feet of gas at 500° F. (260° C.), become over 230,000 cubic feet, and this volume is further increased by 300 to 400 lb. of water per ton of coal in the form of vapour, arising from the hydrogen in the coal, and the water in the materials. Moreover, every ton of coal yields from 120 to 220 lb. of tar, given off partly in the form of vapour at the above temperature, and partly in suspension. Some idea may thus be gained of the enormous gaseous volume per ton of coal issuing from the throat of a coal-fed blast furnace. The gases contain a considerable amount of dust, which should be got rid of before the actual condensation of the tar and ammonia. In recovering ammonia from the waste gases, experience has proved that it is best to maintain an outward pressure on the gas. A suction or inward pressure may not only lead to disastrous explosions, but it very much reduces the yield of ammonia per ton of coal, owing to the entrance of air and the consequent combustion of the ammonia. The tar in these gases is scrubbed out with great difficulty, owing to its peculiar physical condition, and its state of suspension in so large a volume of gases. No amount of cooling and washing is so effective as some form of violent mechanical action, such as dashing with water or otherwise. The different methods for recovering of tar and ammonia from blast furnaces may be grouped as follows:—

If the whole of the gases of all the furnaces at present in blast in Scotland were being treated for the recovery of ammonia, the turn-out of ammonium sulphate would be some 18,000 tons per annum, equal to 22% of the present production of Great Britain. Interesting details of the methods of carrying out the above-named processes are given, for which the original paper must be consulted.

—W. S.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*An Examination of the Phenol Constituents of Blast Furnace Tar obtained by the Alexander and McCosh Process at the Gartsherrie Iron Works.* Watson Smith, J. F. H. Coutts, and H. E. Brothers. Part I. Proc. Chem. Soc., November, 1885.

By agitating the lighter cresote oils of the blast furnace tar with an equal bulk of caustic soda solution of 1.09 sp. gr., etc., the authors have obtained 17.5 per cent. by volume of crude phenols; while from ordinary gas retort tar, and also from Jameson coke oven oil, they have obtained about 5 per cent. However, by more exhaustive treatment with more concentrated soda solution, 23.1 per cent. of phenols were obtained from the blast furnace oil, and about 8 per cent. from the Jameson oil, which seems to be a nearer approach to the shale oil of the paraffin manufacturer; similarly, some 9 or 10 per cent. could be obtained from gas retort coal tar oil.

On fractionating the crude phenols from the blast furnace oil, only 5.63 per cent. by volume distilled over between 180° and 210°, 30.7 per cent. between 210° and 240°, and 18 per cent. between 260° and 300°. During the distillation of the portions boiling below 300°, and especially of the lower boiling portions, much sulphuretted hydrogen was evolved, and afterwards sulphurous oxide; at the same time a considerable amount of sulphur was deposited in the condenser. In fractionating the portion distilling from 300° to the coking point of the residue, when the latter point was reached both hydrocyanic acid and ammonia were evolved.

The phenols having been separated into groups boiling between certain temperatures, and these fractions purified as far as possible, they were distilled over

heated zinc-dust: the hydrocarbons metaxylene, trimethylbenzene (probably pseudocumene), and naphthalene were thus obtained, and from their formation the authors infer the presence of the corresponding phenols in the original oils. Phenol itself was separated in small quantity from the portion distilling between  $180^{\circ}$  and  $210^{\circ}$ , metaresol being the chief constituent of this fraction; metaxylene was one of the most abundant constituents of the portion boiling between  $210^{\circ}$  and  $240^{\circ}$ .

Inasmuch as low temperature tars such as that examined contain extremely little phenol, whereas gas retort tars are comparatively rich in this body, and also because other homologous phenols are so abundantly present in blast furnace tars, it is difficult to accept Schulze's theory as exclusively sufficient to account for so much benzene as is found in gas retort tars. According to this theory, in the formation of aromatic hydrocarbons by the destructive distillation of coal, phenols are primarily formed, and subsequently suffer disruption at higher temperatures, yielding water and aromatic hydrocarbons. This may be the case to some extent, but it is likely that the synthetic reactions indicated in the theories of Berthelot, Jacobson and Anschütz are also largely concerned in the production of the benzenes, naphthalene, anthracene, etc.—W. S.

#### Synthesis of Thiophen and Pyrroline Derivatives. C. Paal. Ber. 18, 2251—2254.

By the action of phosphorus sulphide and of ammonia on acetophenoneacetone the author prepared phenylmethylthiophen and an analogous pyrroline compound. Acetonylacetone ( $\text{CH}_3\text{CO}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}\cdot\text{CH}_3$ ) gives, under the same conditions, dimethylthiophen, or thioxen, and dimethylpyrroline.

**Thioxen.**—Three parts acetonylacetone are heated with two parts of powdered phosphorus pentao- or trisulphide in a sealed tube for one hour at  $140^{\circ}$ – $150^{\circ}$ . On cooling, the thioxen separates as a colourless oil, which may be purified by distillation over sodium. The yield of the product is 50–60 per cent. of the theoretical. B.P.  $134^{\circ}$ – $135^{\circ}$ . With isatin and sulphuric acid it gives a cherry-red colouration; with pheanthrenequinone dissolved in glacial acetic acid a beautiful violet shade.

**Dibromothioxen** may be prepared by adding a solution of bromine in  $\text{CS}_2$  to thioxen dissolved in  $\text{CS}_2$ . On evaporating the  $\text{CS}_2$  a crystalline compound is obtained of the formula  $\text{C}_8\text{H}_6\text{Br}_2\text{S}$ ; M.P.  $97^{\circ}$ .

**Tribromothioxen.**—The dibromo compound dissolves in excess of bromine with evolution of HBr. The product, after recrystallisation, melts at  $142^{\circ}$ – $144^{\circ}$ , and has the formula  $\text{C}_8\text{H}_3\text{Br}_3\text{S}$ .

**Methylthiophenecarboxylic acid** is formed by the oxidation of thioxen with an alkaline solution of potassium permanganate; M.P.  $142^{\circ}$ .

**Dimethylpyrroline** is obtained by heating acetonylacetone with alcoholic ammonia in slight excess in sealed tubes for one hour, at  $150^{\circ}$ . The product is evaporated, and the residue distilled. The liquid boils at  $165^{\circ}$ , and is identical with that obtained by Weidel and Ciamician (Ber. 13, 78) and L. Knorr (Ber. 18, 1558).—J. B. C.

#### Thioxen from Coal-tar. J. Messinger. Ber. 18, 2300—2303.

ACETYLTHIOXEN is obtained by the action of acetyl chloride (Ber. 17, 2643) on pure thioxen in presence of aluminium chloride. 5grms. thioxen are dissolved in 100grms. petroleum spirit, 3.5grms. acetyl chloride added, and  $\text{Al}_2\text{Cl}_6$  slowly introduced. A black oil and thick masses of organic aluminium compounds separate. The yield is improved by heating the mass occasionally on the water-bath after the addition of the  $\text{Al}_2\text{Cl}_6$ . On adding water, the acetylthioxen dissolved in the petroleum spirit swims on the surface, and may be separated by distilling the whole with steam, the receiver being changed when the petro-

leum spirit has passed over. Acetylthioxen is a colourless liquid, B.P.  $223^{\circ}$ – $224^{\circ}$ ; with hydroxylamine it forms a compound of the formula  $\text{C}_8\text{SH}(\text{CH}_3)_2\cdot\text{C}(\text{NOH})\cdot\text{CH}_3$ . By the action of alkaline potassium permanganate, acetylthioxen is oxidised to thiophen-tricarboxylic acid; but the free acid could not be obtained pure. If, however, the product of oxidation be dissolved in ammonia, and the neutral ammonium salt precipitated with silvernitrate, a yellow silver salt is formed, which, on heating with methyl iodide in an ethereal solution, yields the methyl ether of thiophen-tricarboxylic acid— $\text{C}_8\text{SH}(\text{COOCH}_3)_3$ .—J. B. C.

### IV.—COLOURING MATTERS AND DYES.

#### *o*-Xylidine and *o*-Xylenol [1:2:3]. A. Töhl. Ber. 18, 2561—2562.

THE author has prepared the only xylidine hitherto unknown—namely,  $\text{C}_8\text{H}_5(\text{CH}_3)_2\cdot\text{NH}_2$  [1:2:3]. Dibromo-*o*-xylene— $\text{C}_8\text{H}_3(\text{CH}_3)_2\cdot\text{Br}_2$  [1:2:4:5]—was converted by nitration into nitrodibromo-*o*-xylene  $\text{C}_8\text{H}_3(\text{CH}_3)_2\cdot\text{Br}_2(\text{NO}_2)$  [1:2:4:5:3], and the dibromoxylidine obtained by reduction of this was debrominated with sodium-amalgam.

**Nitrodibromo-*o*-xylene**— $\text{C}_8\text{H}_3(\text{CH}_3)_2\cdot\text{Br}_2(\text{NO}_2)$  [1:2:4:5:3]—forms colourless needles of melting point  $141^{\circ}$ .

**Dibromo-*o*-xylidine**— $\text{C}_8\text{H}_3(\text{CH}_3)_2\cdot\text{Br}_2\cdot\text{NH}_2$  [1:2:4:5:3]—crystallises from alcohol in colourless needles, melting at  $103^{\circ}$ .

***o*-Xylidine**— $\text{C}_8\text{H}_5(\text{CH}_3)_2\cdot\text{NH}_2$  [1:2:3]—is a colourless oil, boiling at  $222^{\circ}$ , and remaining fluid at  $15^{\circ}$ . The hydrochloride ( $\text{B}\cdot\text{H}\cdot\text{Cl}=\text{H}\cdot\text{O}$ ) forms large soluble plates, the nitrate ( $\text{B}\cdot\text{H}\cdot\text{NO}_3$ ) easily-soluble long needles, and the sulphate ( $\text{B}\cdot\text{H}\cdot\text{SO}_4$ ) large plates. Its acetyl derivative forms long, fine needles, which melt at  $131^{\circ}$ .

***o*-Xylenol**— $\text{C}_8\text{H}_3(\text{CH}_3)_2\cdot\text{OH}$  [1:2:3]—was obtained from the xylidine by the diazo-reaction. It crystallises from water in long, fine needles, melting at  $75^{\circ}$ , and boiling at  $218^{\circ}$ ; with  $\text{Fe}_2\text{Cl}_6$  it gives a blue colouration.—A. G. G.

#### Derivatives of Pseudocumidine. K. Auwers. Ber. 18, 2655—2663.

THE pseudocumidine  $\text{C}_8\text{H}_5(\text{CH}_3)_2\cdot\text{NH}_2$  [1:3:4:6] was prepared by distilling commercial cumidine and crystallising the fraction  $232^{\circ}$ – $235^{\circ}$  from strong alcohol. It forms large colourless prisms, melting at  $68^{\circ}$  and boiling at  $234^{\circ}$ .

**Acetylpsendocumidine**— $\text{C}_8\text{H}_4(\text{CH}_3)_2\cdot\text{NH}\cdot\text{Ac}$ —obtained by boiling the base with acetic acid for several hours, crystallises in white needles, melting at  $164^{\circ}$  and boiling above  $360^{\circ}$ ; insoluble in cold water.

**Acetylnitrocumidine**— $\text{C}_8\text{H}_4(\text{CH}_3)_2(\text{NO}_2)\cdot\text{NH}\cdot\text{Ac}$ —is formed by nitration of the preceding body in acetic acid solution. It crystallises from alcohol in fine white needles of melting-point  $204^{\circ}$ ; insoluble in cold water.

**Acetyldinitrocumidine**— $\text{C}_8\text{H}_3(\text{CH}_3)_2(\text{NO}_2)_2\cdot\text{NH}\cdot\text{Ac}$  [1:3:4:2:5:6]—is obtained by further nitration of either of the two preceding bodies with a mixture of 6 vols. of fuming  $\text{HNO}_3$  and  $\frac{1}{2}$  vol. of  $\text{H}_2\text{SO}_4$ . It melts at  $280^{\circ}$ , sublimes undecomposed, and is insoluble in water; sparingly soluble in other solvents. On saponification it gives—

**Dinitrocumidine**— $\text{C}_8\text{H}_3(\text{CH}_3)_2(\text{NO}_2)_2\cdot\text{NH}_2$  [1:3:4:2:5:6]—crystallises from alcohol in long orange-yellow needles of melting-point  $183^{\circ}$ .—A. G. G.

#### A New Cumidine. W. Engel. Ber. 18, 2229—2233.

COMMERCIAL cumidine, obtained by heating xylidine-hydrochloride with methyl alcohol for twenty-four hours at  $250^{\circ}\text{C}$ . under a pressure of 20 atmospheres, was treated with HCl, the solid hydrochloride was pressed, treated with an alkali, distilled with steam and fractionated; the fraction  $225^{\circ}$ – $227^{\circ}$  was boiled for twelve hours with acetic acid, and the acetyl derivative recrystallised from water until it had the melting point  $112^{\circ}$ . By saponification of this acetyl derivative the new cumidine  $\text{C}_8\text{H}_5(\text{CH}_3)_2\cdot\text{NH}_2$  was obtained. It can also be isolated by directly acetylating the crude cumidine and crystal-

lising the acetyl derivative. It boils at 224°. The hydrochloride forms white needles easily soluble in water, nearly insoluble in strong HCl; the nitrate is less soluble than the sulphate. The following bodies were prepared from the new cumidine by the ordinary methods:—

*Cuminol*— $C_8H_2(CH_3)_2.OH$ —oily fluid, boiling at 217°.

*Acetyl-nitro-cumidine*— $C_8H(CH_3)_2(NO_2)(NHAc)$ —yellow needles of melting point 121°.

*Acetyl-di-nitro-cumidine*— $C_8(CH_3)_2(NO_2)_2NHAc$ —nearly colourless needles, insoluble in water, melting at 204°.

*Mono-cumyl-urea*— $NH_2.CO.NH.C_6H_2(CH_3)_3$ —white needles, insoluble in water.

*Di-cumyl-urea*— $CO[NH.C_6H_2(CH_3)_3]_2$ —white needles melting above 290°.

*Di-cumyl-thio-urea*— $CS[NH.C_6H_2(CH_3)_3]_2$ —prismatic crystals, insoluble in water, melting point 146°.—A. G. G.

*Action of Acetone on Aniline.* C. Engler and P. Richm. Ber. 18, 2245—2249.

THE authors find that the base ( $C_{11}H_{11}N$ ) which is produced by heating aniline hydrochloride with acetone (with or without a condensing agent) is formed more readily by heating aniline hydrochloride with mesityl oxide at 130°.  $CH_3$  is evolved in both reactions, and the authors consider that the base is a (Py. 1:3)-dimethyl-quinoline:—

It is a colourless fluid of boiling point 264° uncorr. The hydrochloride ( $HCl$ ) sublimes in flat needles easily soluble in water and alcohol. The acid sulphate ( $H_2SO_4$ ) forms soluble needles melting at about 227°. The chromate ( $K_2Cr_2O_7$ ) forms long orange needles, easily soluble in hot water, very sparingly in cold. A similar base is formed by heating aniline hydrochloride with acetophenone.—A. G. G.

*The Relation of Diazobenzene-amidide to Amidazobenzene.* R. J. Friswell and A. G. Green. J. Chem. Soc. (Trans.), December, 1885, 917-924.

AMIDAZOBENZENE, an isomer of diazobenzene-anilide, is usually prepared by allowing the latter body to remain in contact with aniline hydrochloride in solution, either in aniline, which is the most usual process, or occasionally in alcohol.

The change has been considered by Kekulé and others to be due to a double decomposition; but according to Griess, who discovered both bodies, the anilide is formed at a low temperature by the action of nitrous gas upon aniline, and the amido-compound by the same reagent at a high temperature.

The authors have endeavoured to obtain amidazobenzene directly from aniline or its salts, but no matter how the experiments were varied as to temperature, acidity, concentration, solvent, order of mixture, and mass of reacting materials, they found that diazobenzene-anilide was formed first, even where, being in the presence of a quantity of aniline salt and in a hot solution, it rapidly changed into the amido-compound.

They have discovered that treatment of diazobenzene-anilide with weak hydrochloric acid, causes the change, even in the absence of aniline hydrochloride; but they have also found that both this acid and dilute nitric acid have the power of resolving the anilide into diazobenzene and aniline chlorides; and they have observed that such mixtures by lapse of time combined again into amidazobenzene, though if the acid were neutralised so as to cause a quick union the anilide was regenerated. From these and other facts detailed in the paper, it is inferred that neither is the isomeric change a double decomposition, nor is it due to coercive action of the acid tending to the development of a base from an indifferent body—strong acids such as oxalic and sulphuric being unable to produce the change. On the other hand, all the evidence points to time as being absolutely essential for the

rearrangement of the molecule. At the same time, they are unable at present to account for the remarkable fact that amidazobenzene can only result from a second stage reaction. It is apparently necessary for the union to take place, so as to form the anilide; this body having been formed, slowly decomposes into diazobenzene and aniline, which then slowly only react, forming amidazobenzene. If their reunion is hastened the anilide is simply reformed.

The resolution of the anilide and the presence of the products in the solution, account for the various decomposition products noticed as accompanying the formation of amidazobenzene.

A similar isomeric change produced by an acid has been described by Wallach and Belli in the transformation of azoxybenzene into oxyazobenzene by means of sulphuric acid. This change the authors think will probably prove to be analogous to the one now discussed, and agreeing with V. Meyer's opinion as to the necessity for a symmetrical formula for diazobenzene-anilide, they think that one formed on the type of the azoxybenzene formula to be open to little or no objection, thus:

*Compounds of Thiophen.* O. Stadler. Ber. 18, 2316.

THIOPHENINE hydrochloride is obtained by precipitating the tin double salt (Ber. 18, 1490) with  $H_2S$  (this Journal, iv. 583). On spontaneous evaporation in vacuo over  $H_2SO_4$ , a white crystalline salt is deposited. The action of acetyl chloride on the above salt produces a coloured mass possessing the metallic copper appearance of certain aniline colours. The product could not be purified. Diazobenzene chloride acts on thiophenine hydrochloride in a concentrated aqueous solution and a yellow crystalline precipitate is formed. The compound is an azo-body of the formula:—

With  $\alpha$ -diazonaphthalene an analogous compound is formed which dyes silk a fast colour. With diazobenzene-sulphonic acid a colouring matter is at once formed. It separates out in the form of yellow needles and colours silk yellow. The above reactions show that thiophenine unlike aniline forms preferably, not diazo-amido, but azo-compounds.

*Nitro-Thiocol:*—One gram, of the above tin double-salt is dissolved in 150cc. water and the tin precipitated with 5cc. of dilute sulphuric acid. The filtrate cooled with ice is treated with the equivalent quantity of  $KNO_3$ . The mass is finally heated on the water-bath and then extracted with ether. The ethereal solution, on evaporation, leaves a yellow crystalline mass, which on recrystallisation melts at 115–116°, and is similar in appearance to paranitrophenol, dissolving in alkalis with a yellow colour. It has the formula:—

An attempt to prepare a dimethyl thiophenine by the action of methyl alcohol on the hydrochloride of thiophenine resulted in the production of methyl mercaptan.—J. B. C.

*On the Formation of Ortho- and Paranitrocinnamaldehyde.* L. Diehl and A. Einhorn. Ber. 18, 2335–2338.

THE authors have prepared orthonitrocinnamaldehyde by the method described by Kinkelin for the corresponding meta compound (Ber. 18, 453); but the yield was only 40 per cent. of the calculated amount, while by the method of Baeyer and Drewsen 70 per cent. were obtained. Following Kinkelin's directions 50grms. of orthonitrobenzaldehyde were dissolved in 800grms. of alcohol; to the solution 1500grms. of water were added, and about 16grms. of acetaldehyde. 30grms. of 10 per cent. caustic soda were gradually added, the liquid never being allowed to become alkaline. After several hours about 5grms. more caustic soda were added.

The greater part of the orthonitrocinnamaldehyde separated out, and the mother liquor after filtration was treated with sodium chloride and extracted with ether. On boiling the residue from the evaporation of the etheric extract with acetic anhydride, more orthonitrocinnamaldehyde was obtained. The purified product crystallised in needles melting at 127–127.5°. The authors have succeeded in preparing ortho- and paranitrocinnamaldehyde by the direct nitration of commercial cinnamaldehyde. To a mixture of 500grms. of concentrated sulphuric acid and 20grms. of potassium nitrate, 25grms. of cinnamaldehyde are added drop by drop, the mixture being kept moderately cool. When the liquid is poured into water the two nitro-compounds separate in flakes, and may be recrystallised from hot alcohol. The separation is best effected by means of the acid sulphites which are formed by the addition of an equal volume of a solution of sodium bisulphite to the hot alcoholic solution of the nitro compounds, the mixture being allowed to cool at once. The greater part of the para-compound separates at once, and the remainder is precipitated by the addition of much sodium chloride. After twelve hours the mixture is filtered when the filtrate contains only the ortho-compound. The para compound is dissolved in water and treated with concentrated sulphuric acid, when most of the nitrocinnamaldehyde is precipitated in flakes, the remainder being extracted with benzene. The pure product crystallises in almost colourless needles melting at 141–142°. The composition was confirmed by analysis. When a solution of the aldehyde in acetic acid is treated with phenylhydrazine an orange-red crystalline product is obtained, melting at 180–181°. The para-compound, dissolved in dilute alcohol, is easily reduced by ferrous sulphate and ammonia. The filtrate is extracted with ether, which on evaporation leaves a brown-red body possessing metallic lustre, and dissolving in sulphuric acid to form a fuchsian-red solution. The ortho-compound is separated and purified in the same way, and forms fine needles, melting at 127–127.5°. The phenylhydrazine compound forms Bordeaux-coloured needles which melt at 157.5°.—S. Y.

*New Method for Preparing Tribenzylamine.* R. Leuckart. Ber. 18, 2341–2344.

ROTH has prepared benzylendiacetimidide by the action of benzaldehyde on acetamide. With formamide the reaction proceeds otherwise. If benzaldehyde be heated with rather more than an equal weight of formamide or ammonium formate on the oil bath, when the temperature reaches 180° a reaction begins with evolution of ammonium carbonate, and a solid body slowly separates out. After heating for several hours the mass is filtered, washed with water and dilute NaOH, and then boiled with alcohol or extracted with ether. The basic products dissolve and a white crystalline substance remains behind, which has not been further studied. The ethereal solution on evaporation and addition of alcohol, crystallises in white plates. This body has the formula  $C_6H_5N$  m.p. 91°. It forms a hydrochloride and a double platinum salt, and is identical in its properties with tribenzylamine. The yield amounts to 50 per cent. of the benzaldehyde used.—J. B. C.

*Metalinitro-azoxybenzene and o-Azoxytoluene.* H. Klinger and R. Pitschke. Ber. 18, 2551–2556.

was obtained by adding a solution of 2½ parts of *m*-di-nitro-benzene in 15 parts of methyl alcohol to a solution of sodium methylate obtained by dissolving one part of sodium in twenty parts of methyl alcohol. After recrystallisation it forms long light yellow needles of melting-point 142°, very sparingly soluble in cold alcohol, easily soluble in benzene.

By heating with strong  $H_2SO_4$  it is converted into the isomeric body di-nitro-hydroxy-azo-benzene,  $C_6H_4(NO_2)-N_2-C_6H_3(NO_2)OH$ ,

which forms yellow crystals of melting point 173°, soluble in alkalis.

prepared by adding ten parts of *o*-nitro-toluene to a solution of five parts of sodium in fifty parts of methyl alcohol, the mixture being finally heated on a water-bath for three or four hours to complete the reaction. The azoxy-toluene forms light yellow needles, plates, or tables, melting at 60°. On distillation with iron-powder it yields *o*-azo-toluene and a little *o*-toluidine. Strong  $H_2SO_4$  converts it into *o*-azo-toluene and an acid compound.—A. G. G.

*Condensation Products of Isatin.* A. Baeyer and M. J. Lazarus. Ber. 18, 2637–2643.

INDOPHENIN, the condensation product of isatin and thiophen, has been again prepared and analysed by the authors as well as dibromindophenin from dibromisatin. The former body has the formula  $C_{12}H_7Br_2NOS$ . Although pure benzene has no action on isatin in presence of strong sulphuric acid, toluene reacts, at once forming a condensation product of the formula  $C_{12}H_9NO$ . The authors consider this compound to be a derivative of pseudoisatin from its analogy with oxindol:

Isatin readily forms condensation products with phenols in presence of sulphuric acid, whereby the two H atoms in oxindol are replaced by two phenol groups. In this way phenol- and anisol-isatin have been prepared. Isatin also combines with tertiary bases, such as dimethylaniline to form dimethylaniline-isatin. These products may also be graphically represented as derivatives of triphenylmethane, from which the analogy with rosaniline and aurin is apparent:

—J. B. C.

*Paraxylidine.* E. Nölting, O. N. Witt, and S. Forcl. Ber. 18, 2644–2668.

THE authors have isolated from commercial xylidine, which was supposed to consist principally of the meta-compound, about twenty-five per cent. of paraxylidine. The method of preparation is as follows: Commercial xylidine is treated with fuming sulphuric acid, and converted thereby into the sulphonic acid. On pouring the cooled mass into water, meta-xylidine separates out as a crystalline mass. The mother liquor is neutralised with lime, and the lime salt converted into sodium xylidinesulphonate. On distillation the salt yields, with very slight loss by decomposition, pure *p*-xylidine. It boils at 212–212.5°. The constitution of this body was determined by converting it into the diazo-compound, and finally into iodoxyene, from which by reduction with sodium amalgam a xylene was obtained, yielding on oxidation terephthalic acid. A number of its derivatives have been prepared. By nitrifying the acetyl compound nitroxylidine is obtained, which on reduction gives xylenediamine. The properties of this body pronounce it a paradiamine. On oxidation it yields para-xyloloquinone (phlorone). If nitro *p*-xylidine be treated with ethyl-nitrite in the usual way, instead of the nitro-hydrocarbon, the ethyl ether is obtained. The diazo-compound of the para-xylidine mentioned above combines with phenols and amines to form beautifully crystalline azo coloring matters. The authors find that the average sample of commercial xylidine contains twenty-five per cent. of the para-compound, which implies also that commercial xylene contains a larger percentage of para-xylene than hitherto admitted.

—J. B. C.

*The Six Isomeric Xylidines.\** E. Nötling and S. Forel.  
Ber. 18, 2668—2681.

*Ortho-xylidines.* By the nitrication of *o*-xylene a nitro-xylidine is obtained, distilling between 225° and 255°, about forty per cent. boiling at 245—247°. This fraction does not crystallise on cooling below 0°. On reduction it yields an amido-compound, which is purified by recrystallising the acetyl derivative from benzene. The fraction of the nitro-xylene boiling above 247° solidifies on cooling, and has a melting point 29—30°. It is therefore identical with Jacobsen's product (Ber. 17, 159); *o*-xylene, like toluene, therefore, yields two mononitro-derivatives—the one a liquid, the other a solid. According to Jacobsen, the solid *o*-nitro-compound has the constitution  $\text{Ph}(\text{CH}_2)_2\text{NO}_2(\text{CH}_2)_2(\text{CH}_2)_2\text{NO}_2=1:2:4$ , and the liquid must therefore be  $\text{Ph}(\text{CH}_2)_2\text{NO}_2(\text{CH}_2)_2(\text{CH}_2)_2\text{NO}_2=1:2:3$ .

*o*-xylidine, obtained by reducing the liquid nitro-xylene, yields on oxidation xyloquinone, and the latter by reduction xyloquinol. By means of the diazo reaction *o*-xylidine has been obtained.

*Meta-xylidines.* The three isomeric *m*-xylidines have been prepared, the *u*-compound  $\text{Ph}(\text{CH}_2)_2\text{NH}_2(\text{CH}_2)_2(\text{CH}_2)_2\text{NH}_2=1:3:5$  from commercial xylidine by recrystallising the hydrochloride and again the acetyl derivative. The other two isomers have been obtained by Wroblewski and Schnitz, the *s*-compound from nitro-xylidine  $\text{Ph}(\text{CH}_2)_2\text{NH}_2\text{NO}_2(\text{CH}_2)_2(\text{CH}_2)_2\text{NO}_2=1:3:5$  by eliminating the amido-group, the *v*-xylidine by distilling amido-mesitic acid with lime. To prepare pure *m*-xylene from the commercial product, it is partially oxidised with nitric acid, which first attacks any *p*-xylene present. On nitrication 68 per cent. of mononitro-*m*-xylene was obtained, boiling between 215° and 241°.

The fraction 215—239° was refracted. All the fractions thus obtained gave, on reduction, the same base, boiling at 209—213°. This *v*-xylidine may be purified by converting it into the acetyl derivative, recrystallising and decomposing the product with HCl in sealed tubes. It then boils at 214° under 739mm. pressure.

*u*-xylidine was prepared from the fraction of nitro-*m*-xylene boiling above 239°. It is the chief product in commercial xylidine. The acetyl derivative melts at 129°. This melting point is considered by the authors as the best criterion of the purity of the base.

*s*-xylidine. This compound was obtained by Wroblewski's method. The acetyl derivative of *u*-xylidine is nitrified, and after separation the compound of the formula,  $\text{Ph}(\text{CH}_2)_2\text{NH}_2\text{NO}_2(\text{CH}_2)_2(\text{CH}_2)_2\text{NH}_2\text{NO}_2=1:3:4:5$  obtained. By the diazo reaction, the amido group is then eliminated. *s*-xylidine yields on nitrication *p*-nitro-*s*-xylidine,  $\text{Ph}(\text{CH}_2)_2\text{NH}_2\text{NO}_2(\text{CH}_2)_2(\text{CH}_2)_2\text{NH}_2\text{NO}_2=1:3:5:4$ .

*Para-xylidine* is obtained by nitrifying *p*-xylene, and reducing the nitro body thus produced with iron and acetic acid.

By heating the different xylidine hydrochlorides with methyl alcohol in sealed tubes to 300—320°, a number of isomeric cumidines have been obtained. This portion of the subject has not yet been completed.—J. B. C.

*The Manufacture of New Colour-yielding Products, and of Colouring Matters therefrom.* Drs. Leo Gans and Meinhard Hoffmann, Frankfurt-on-the-Main, Germany.  
Eng. Pat. 816, January 5, 1884.

This is an amendment of the former patent, No. 816 of 1884, the chief alteration being the statement referring to the nature of the by-products obtained by heating  $\beta$ -naphthylsulphonic acid with sulphuric acid to 60° C. for thirty-six hours. The chief product is, as formerly claimed,  $\beta$ -naphthol- $\gamma$ -disulphonic acid, but the by-product is not as stated in the previous specification, chiefly Schaller's monosulphonic acid, since on a large scale a mixture of sulphonic acid is formed.—R. M.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*Process and Apparatus for Treating Textile Materials with Liquids or Gases.* H. J. Haddan. From Brandt and v. Nuwrocki, Agents for C. Wetser, Thunn, Alsace.  
Eng. Pat. 15,654, November 27, 1884.

THIS patent relates to a process and apparatus for scouring, bleaching, or dyeing all kinds of textile materials at any stage of manufacture, whether yarns, cops, or woven goods, by subjecting them in hermetically closed vessels to the action of hot or cold liquids under direct pressure in combination with—

(a.) A continuous or intermittent circulation of the liquid.

(b.) A vacuum produced in the apparatus.

(c.) A vacuum produced in the apparatus in conjunction with continuous or intermittent circulation of the liquid.

The patentee recommends different forms of apparatus, of which he gives drawings, for the different materials to be treated. The cops, if required, can be scoured, bleached and dyed without being removed from the apparatus, or being dried between the operations, by means of an ingenious arrangement of mounting them on hollow spindles inside the vessels.—J. H. H.

*Improvements in Machines for the Washing, Cleansing, and Scouring of Wool and other Fibrous Material.* John Petrie and Frederick William Petrie. Eng. Pat. 1519, February 4, 1885.

THIS invention relates to an apparatus for the continuous application of the detergent solution employed for scouring wool or other fibrous material. It consists of a tank to collect the excess of liquid expressed from the material by means of the squeezing rolls ordinarily employed in cleaning wool. The tank is furnished with a float, attached to which is a rod fitted with two adjustable collars. The whole is arranged in such a way that on the rising of the float one of the collars acts on a lever connected with a steam injector, thereby causing the latter to raise the liquor in the tank and return it to the squeezing rolls. When in this way the level of the liquor in the tank is lowered, the other collar shuts off the steam from the injector. The supply of liquor to the squeezing rolls is thus made automatic.—E. J. B.

*Improvements relating to the Waterproofing and Preservation of Linen and other Fabrics, Ropes, Hose, and other Articles composed of Vegetable Substances.* H. H. Lake. From A. Sandron, Menin, Belgium.  
Eng. Pat. 6509, May 28, 1885.

THE inventor first steeps his linen or other goods in a solution of chestnut extract—or extract of other substance rich in tannin—at from 1½° to 3° Tw. When the fabric is thoroughly saturated it is dried, and is then immersed in a second bath, consisting of twelve parts each of a pigment—as required—and of boiled linseed oil; two parts of birch-bark tar; and one part of palm-wax. This bath is maintained at a temperature of 100—120° C. (230° F.), and the goods on emerging from it are passed between squeeze rollers to remove excess of liquid. A further quick passage through a bath of cold boiled linseed oil gives the goods a better appearance. The inventor claims that goods so treated are impermeable and impudrescible, neither sticky nor brittle, and that the original good qualities of the material are not impaired.—J. H. H.

*Process for Scouring Wool.* Charles Toppan. Eng. Pat. July 28, 1885. Complete Specification.

THE inventor claims the use of a solution prepared by dissolving together in water, mustard-seed oil, petroleum or other mineral oils, and alkali. Wool scoured by this solution is more pliable, has greater strength, and can be more finely spun than wool prepared by the ordinary methods.—E. J. B.

\* *v*=adjacent, *s*=symmetrical, *a*=asymmetrical.

*An Improved Waterproof Cloth.* W. H. Slade. Eng. Pat. 10,554, September 7, 1885.

THE only novelty in this patent is the use of a "one-sided Terry cloth" for waterproofing. There is nothing new in the manner of applying the waterproofing substance, and the inventor does not state its composition.—J. H. H.

*Improvements in Obtaining and Treating Fibres from the Barks of Plants of the Urtica family, and the like.* G. F. Redfern. From Prof. C. Fremy and V. Urbain, Paris. Eng. Pat. 11,660, September 30, 1885.

THE inventors state that to the presence of lime—of which there is from three to eight per cent. in the outer covering of the plant—is due the brittleness and absence of gloss which is a frequent cause of depreciation in the value of the fabrics obtained from plants of the Urtica (nettle, rhea, etc.) family, and the like. To eliminate this, the bark of the plants is detached from the woody portion—preferably by Favier's process (Eng. Pat. 1609, 1880)—and then steeped for one day in a cold solution of HCl at 3° Tw., which is the distinctive feature of the process. It is then washed thoroughly, and boiled in kiers at a pressure of three atmospheres with a solution of caustic soda at 2° Tw. This operation may be repeated if necessary, and the fibre is next washed and again soaked in HCl at 3° Tw. for fifteen minutes; then washed again and heated for three hours in the kier, with a solution containing 1 lb. of caustic soda and 9½ oz. of oleic acid to every ten gallons of water. The inventors claim that by this process all the lime is removed, and the fabric sufficiently bleached, without the use and deteriorating influence of bleaching powder.—J. H. H.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Improvements in the Apparatus to be used in Bleaching Fabrics and Yarns.* William Mather. Eng. Pat. 16,663, December 19, 1884.

THE object of this invention is to facilitate and accelerate the operation of bleaching as performed by the Thompson process. The apparatus consists of a cylindrical bleaching kier, connected by means of a three-way cock with a pump, a tank for holding liquor, and a gas-holder containing carbonic acid gas. The kier is furnished with a cover fitting into an annular space filled with water, thus ensuring a perfectly gas-tight joint. By the simple manipulations of the three-way cock, the kier can be successively filled either with bleach liquor or with gas.—E. J. B.

*Improvements in the Extraction of Extraneous Matters from and in Bleaching Vegetable Fibres.* Jonathan Smith and Philip Winter Nicholle. Eng. Pat. 17,083, December 31, 1884.

THIS process consists in treating fibres, such as China-grass, manilla, etc., with a solution of an alkaline sulphate, either hot or cold. The fibre is then washed, soaked in a weak acid solution, and finally bleached with a solution prepared by decomposing chloride of lime with sulphate of potash.—E. J. B.

## VII.—ACIDS, ALKALIS, AND SALTS.

*The Occurrence of Springs containing Carbon Dioxide, and the Preparation of Liquid Carbonic Acid at Burghöhl.* Abstract of a paper read by Mr. Heusler at the meeting of the Society of Natural History and Medicine at Bonn.

SOME time ago a shaft 52 metres deep was sunk at Burghöhl, and at Hoenningen on the Rhine, from which considerable quantities of carbon dioxide and water saturated with that gas, may be obtained. Measurements recently taken showed that the bore-hole yielded 430 litres of water and 1500 litres of carbon dioxide per

minute, equal to 2160 cubic metres per twenty-four hours. As soon as it was proved that a permanent supply of gas could be expected, a factory for compressing the carbon dioxide evolved was started, and has been working for the last six months. The apparatus consists of a boiler and steam-engine. The engine works two gas-compressors, whence the compressed carbon dioxide is passed into a worm lying in cold water. Wrought-iron cylinders are screwed to the worm, and serve to receive the liquid carbonic acid. 500 litres of carbon dioxide yield 1 litre of liquid carbon dioxide, weighing 1 kilo. The pressure necessary for the compression is equal to 49 atmospheres at 13° C., or to 60 atmospheres at 21·5° C. The cylindrical bottles serving for the conveyance of the finished product hold 8 litres or 8 kilos, each, and are tested for a pressure of 250 atmospheres. Explosions of bottles occur very rarely. They are not dangerous either, as the material cracks without flying asunder, thus only causing a vehement evolution of gas. The explosions would become dangerous only under special circumstances; for instance, if the bottles became warm or hot, which circumstance would cause an enormous increase of the pressure; for whereas air expands for a rise of temperature from 0° to 30° C., by 0·109 of its volume, liquid carbonic acid increases its volume four times as much, or 0·423 of its volume. This curious property of liquid carbonic acid has been applied in practice for the compression of steel and other metal castings. At Krupp's steel works at Essen the enormous pressure of 1200 atmospheres has been reached when heating liquid carbonic acid to 200° C.—S. H.

*The Decomposition of Potassium Chlorate by Heat.* Frank L. Teed. Proc. Chem. Soc., November, 1885.

By heating potassium chlorate till it had lost varying amounts of oxygen, determining that oxygen from the loss in weight, and determining the potassium chloride produced by means of a decinormal silver nitrate solution, using potassium chromate as indicator, the author has come to the conclusion that potassium chlorate decomposes according to the equation:

The equation indicates that for every 74·5 parts of potassium chlorate produced, there should be 24 parts of oxygen evolved; also that when potassium chlorate shall have yielded 7·84 per cent. of oxygen, all the chlorate is decomposed, and nothing but perchlorate and chloride are left.

The equation  $2\text{KClO}_3 = \text{KClO}_4 + \text{KCl} + \text{O}_2$ , by which the decomposition is ordinarily expressed, requires 32 parts of oxygen to every 74·5 of potassium chlorate, and would not be complete till 13·06 per cent. of the oxygen had been evolved.

The following are results obtained:—

Amount of KClO <sub>3</sub> taken. Grams.	Oxygen lost, per cent.	Potassium Chloride formed, per cent.	Amount of Oxygen to 74·5 of KCl.
3·2515	1·66	5·26	23·51
1·592	3·49	10·86	23·94
2·1725	6·00	18·25	24·19
3·956	10·32	27·36	28·65

The last experiment, in which 10·32 per cent. of oxygen was evolved, shows a much larger yield of oxygen to the 74·5 parts of potassium chlorate, which is readily explainable by reference to the equation proposed. As mentioned above, the change represented by the equation is finished when 7·84 per cent. of oxygen is evolved, and 24·34 per cent. potassium chloride is produced. The remaining 2·68 per cent. of oxygen can only be produced by the decomposition of potassium perchlorate in accordance with the equation  $\text{KClO}_4 = \text{KCl} + 2\text{O}_2$ ; from this it follows that 74·5 parts potassium chloride are produced for every 64 of oxygen, and hence that the

evolution of 2.68 of oxygen should be accompanied by the formation of 3.14 of potassium chloride. Therefore 10.52 of oxygen requires  $24.34 + 3.14 = 27.48$  of potassium chloride, a number agreeing fairly well with that found—27.36.

On treating some of the residue from the fourth experiment with sulphuric acid, only the faintest possible indication of a chlorate was obtained.

The author confirms the statement that no perchlorate is formed when potassium chlorate is heated with manganese dioxide, having found in one experiment—the only one made—a ratio of 74.5 of potassium chloride to 47.15 of oxygen (theory requiring 48), when the amount of oxygen evolved was only 3.38 per cent.

If potassium perchlorate be required in quantity, it would be considerably better to heat the chlorate till only 7.84 per cent. than till 13 per cent. of oxygen is evolved, as the equation  $2\text{KClO}_3 = \text{KClO}_4 + \text{KCl} + \text{O}_2$  indicates a yield of 56.53 per cent. of perchlorate; the equation  $10\text{KClO}_3 = 6\text{KClO}_4 + 4\text{KCl} + 3\text{O}_2$ , a yield of 67.84 per cent.—W. S.

#### *Machinery for the Manufacture of Nitrate of Soda.* Robert Harvey. Proc. Inst. C.E., 1884—85. Part iv.

THE whole of the known nitrate deposits in the world are situated on the west coast of South America, between south latitude 19 and 27°, although there are indications of nitrate in Nevada and California. The "caliche," or raw nitrate of soda, is supposed to have originated from decomposing animal and vegetable matter in contact with salts left by the evaporation of sea-water, and this theory is supported by the frequent discovery of guano, feathers, shells, etc., in proximity to the caliche, and at a depth of 12 to 15 feet below the surface. The best deposits are found on the Tamarugal Pampa, in the province of Tarapacá, recently annexed by Chile. The caliche is found in beds from six inches to twelve feet thick, beneath a covering of conglomerate. No caliche

reached 570,000 tons. Such a production would have created an excess over the demand, and the producers have since agreed to limit their output so as to meet European requirements, which at present are 460,000 tons annually. The production of English Companies amounts to 40 per cent. of the whole. A description is given of the plant erected by the author at the Ramirez Factory, Northern Chili, of which the productive capacity is 6360 tons per month; but, like the other establishments, this factory is limited to 40 per cent. of its full capacity, and this gives an annual output of 30,000 tons. The plant comprises six steel boilers, twelve boiling tanks, ninety crystallising tanks, a five-compartment washing tank, three large circular tanks, and three crushing machines, as well as locomotives and rolling stock. Owing to the salt and other solvents contained in the soil, great care was bestowed in preparing the foundations for the carrying walls. The caliche is extracted according to the Slangs' lixiviating system, and when the solution is at 110° F. it is allowed to settle for a short time, and then is run off to the crystallisation tanks at a temperature of 240° F. The crystallised nitrate, after the mother-liquor has drained away, is transferred to drying floors, where it becomes perfectly dry in the tropical sun, and it is then filled into sacks for export. The cost of the machinery, plant, and construction amounted to £110,000. For the night work, two 6000 candle-power arc lights are used. The paper is accompanied by drawings showing arrangement of plant.—G. H. B.

#### *A New or Improved Method of Manufacturing the Fluoride, or Double Fluoride, of Aluminium with Sodium or Potassium.* L. A. Groth, London. From R. Gatzel, Hanover. Eng. Pat. 156, January 5, 1885.

SOLUTIONS of 1 equivalent of aluminium chloride and 6 equivalents of an alkaline fluoride are mixed together. Aluminium fluoride is precipitated, and an alkaline

bed is found nearer to the sea coast than 15 miles, and the furthest beds are distant 90 miles. The Ramirez caliche is plentiful and easy of extraction; it contains 51 per cent. nitrate of soda, 26 per cent. common salt, 6 per cent. sulphate of soda, 3 per cent. sulphate of magnesia, and 14 per cent. insoluble. The figure shows the position of the caliche in the ground, and the method of obtaining it. A shaft, about one foot in diameter, is sunk, into which a boy is lowered, who forms a cone-shaped recess in the earth at the bottom of the caliche, which is charged with a slow-blasting powder, and ignited by a fuse. This causes a dull explosion, loosening the ground around the shaft for a radius of ten yards. The production of nitrate of soda has been developed with great rapidity since 1869, only 6000 tons having been exported in 1845. The production increased by degrees up to 70,000 tons in 1859, and in 1883 the exportation

chloride remains in solution. When a larger proportion of alkaline fluoride is present, the excess combines with the aluminium fluoride produced, to form a double fluoride. When a double fluoride of aluminium and an alkali metal, such as cryolite, is finely powdered and treated with aluminium chloride solution, the alkaline fluoride reacts as above, the aluminium fluoride remaining with the insoluble precipitate of the newly-formed like substance.—A. R. D.

#### *Improvements relating to the Treatment of Alkaline Silicates and other Materials, and to the Formation of various Articles therefrom.* W. R. Lake, London. From the Bowsilite Company, Limited, of Albany, New York. Eng. Pat. 5553, May 5, 1885.

To a filtered solution of alkaline silicate of 26° B., a solution of camphor in turpentine is added, and the

whole evaporated on a water-bath to such a consistency that when cold it can be ground to powder, and does not adhere to the dies in the process of moulding. The ground material is placed in dies or moulds of the usual construction, and subjected to a pressure of 2000 lb. to the square inch, at a temperature of from 250° to 300° F. The articles, when taken from the mould, are polished, and then immersed in a bath of chloride of ammonium solution for from ten to fifteen hours, to correct the tendency of the material to effloresce. The turpentine may be omitted, and the silicate used either by itself or with the admixture of some suitable oxide, as zinc oxide, or inert colouring matter. In this case the articles should be subjected to the pressure of about 8000 lb. per square inch. This material may be largely used as a substitute for ivory.—A. R. D.

*Improvements in the Manufacture of Hydrates of Barium and Strontium.* Hugh Lee Pattinson, jun., Felling-on-Tyne. Eng. Pat. 16,959, December 28, 1885.

To a solution of the sulphide, say of barium, oxide of manganese is added, and air is blown through the mixture. About 66 per cent. of the barium are converted into hydrate, and about 33 per cent. into insoluble hyposulphite. Also about 33 per cent. of the sulphur present are liberated and deposited. This sulphur is separated from the rest of the precipitate by a suitable solvent, preferably naphtha, and the oxide of manganese used to convert a fresh batch of sulphide solution. The impregnation with naphtha enables 80 per cent. of the barium to be converted into hydrate by checking the formation of hyposulphite. By a modification of the invention, air is blown into the mixture as above, only till a precipitate begins to form. At this point, two-thirds of the barium exists in the form of hydrate, and the remaining third, probably, as tersulphide. The clear liquor is allowed to crystallise, and yields almost pure barium hydrate; the mother-liquor is evaporated down, and the barium tersulphide so obtained is reduced to sulphide by any convenient process, and treated as above.

months of about 10 per cent. It is noticeable that of this make no less than 600,183 tons was ingot iron containing under 0.18 per cent. of carbon, used for wire, sleepers, tin plates, tubes, boiler and ship plates, etc. The makes of the various countries are as follow:—

	Tons	Tons
England	115,767	Of this 70,813 contained under 18% carbon.
Germany	617,511	121,862
Austria	130,582	62,330
France	51,514	42,118
Belgium and other Countries		
Total	915,317	600,183 Tons.

*The Influence of Silicon on the Properties of Cast Iron:* Part II. Thomas Turner. J. Chem. Soc. (Trans.), December, 1885, 902—916.

THE paper is a continuation of one recently published (*Chem. Soc. Trans.*, 1885, 577, and this *Journal*, iv. (10), 595).

An account is given of experiments on the relative density, hardness, working qualities, and crushing strength of the metal, and the reason of the variations noticed is discussed.

The relative density was determined both in mass and in small fragments. In the first case, cylinders 3" x 1" were employed, and the turnings from the cylinders were used for a second determination. In iron possessing great tenacity, the density was slightly increased; but with less tenacity, the density was decreased by the force exerted in turning the metal. The hardness was measured by the weight in grains necessary to produce a scratch with a cutting diamond. The influence of silicon is shown to be quite regular, the greatest softness being produced by from 2 to 3 per cent. The working qualities are taken from the observation of a skilled workman, and agree very closely with the hardness as before determined. The crushing strength tests were performed

Silicon per cent.	Relative density* of cylinders 3 x 1.	Relative density* of turnings from cylinders.	Relative hardness.	Crushing strength. Breaking load per sq. in.	
				Pounds.	Tons.
0	7.560	7.719	72	168,700	75.30

\* Water at 20° C. = 1.

over again. During the blowing process, the temperature should be kept at about 100° F., and the formula  $MnO_2 + BaS$  should represent the proportions of manganese and sulphide of barium used.—A. R. D.

## X.—METALLURGY, Etc.

*Progress of the Basic or Thomas-Gilchrist Process, for Twelve Months ending September 30, 1885.*

THE total make of steel and ingot iron made from phosphoric pig during this period amounts to 945,317 tons, being an increase over the make for the previous twelve

by Prof. Kennedy on cylinders 3" x 0.75", and sketches are given of the fractured specimens. The influence is tolerably regular, and of the kind previously observed: the maximum value being reached with 1 per cent. of silicon.

In the above table a summary is given of the chief results.

The author draws the following conclusions from these results.

1. That a suitable small addition of silicon to cast-iron almost entirely free from silicon, is capable of producing a considerable improvement in the mechanical properties of the metal.

2. That in these experiments the maximum values are probably reached with the following amounts of silicon:

Crushing strength .....	about 0.80 per cent.
Modulus of elasticity .....	" 1.00 "
Relative density (in mass) ....	" 1.00 "
Tensile strength .....	" 1.80 "
Softness and working qualities ..	" 2.50 "

3. That when general strength is required the amount of silicon should not vary much from about 1.4 per cent.; but that when special softness and fluidity are desirable, about 2.5 per cent. may be added. Even in the latter case, however, any increase upon 3 per cent. must be dangerous.

These conclusions are only strictly true under the circumstances of the author's experiments, but he hopes shortly to bring forward evidence from independent investigations to support his results.

The cause of these results is discussed. The author is decidedly of the opinion that the production of graphitic carbon is not the only cause of these differences, but that in addition to the indirect effect owing to the production of grey iron, the suitable addition of silicon has a direct and beneficial influence upon the mechanical properties of the metal.—W. S.

*Processes for the Treating of Metals, for their Coating and Insulating with Vitreous, Similar, and other Substances, and in heating and fusing by portable and manifold means upon such Metals and Materials.* William Adolphus Biddell, Erdington, and Caroline Aris Biddell, Islington. Eng. Pat. 13,029, October 1, 1884.

This patent refers to means for coating iron or steel surfaces with vitreous enamels for various purposes and by various methods enumerated.—W. G. M.

*Improvements in the Manufacture and Treatment of Self-hardening Steel.* Robert Hadfield, Southampton Buildings, London. Eng. Pat. 16,049, December 6, 1884.

IRON or steel scrap, or wholly or partially decarburised pig iron, is melted with a proportion of ferro-manganese-silicon or spiegel in such proportions that the manganese is present in the resulting product to the extent of from 2½ to 7 per cent., the carbon being preferably kept low. To obtain the maximum hardness, 2½ to 5 per cent. of manganese should be present; for a less hard metal, from 5 to 7 per cent. This steel, which may be made containing only one-half per cent. of carbon, is less liable than ordinary steel to honey-combing and to slag impurities; and, although very hard in the cold, works mild, and when being reduced will bear with safety a higher temperature than that commonly employed; it is less expensive than tungsten and other self-hardening steels.—W. G. M.

*A New or Improved Method of Plating Silver with Gold.* John Millward Banks, Birmingham. Eng. Pat. 16,855, December 23, 1884.

Two plates of silver and gold respectively, of equal size and of thicknesses proportional to those ultimately required (e.g., for jewellery ornaments, the plates might be 8 inches long by 4 inches wide, the sheet of silver being nineteen times thicker than that of gold) are rendered perfectly flat and absolutely clean. They are then placed in intimate contact between two somewhat larger plates of iron clamped together by binding with wire at the projecting edges. The whole mass is then heated to a bright red heat in a muffle containing pieces of coke, to prevent oxidation of the iron plates, and is then submitted to powerful pressure in a suitable press with flat bed plate; the object being merely to unite the faces of the heated metals. It is then raised carefully to a temperature approaching the fusing point of silver—a point indicated by the appearance of a bright line at the junction of the plates, or by the fusion of a suitable silver alloy placed in a cupel close to the mass. The compound plate may afterwards be rolled to any degree of fineness.—W. G. M.

*An Improved Instrument or Apparatus for Indicating the Presence of Gas, being more particularly applicable for use in Coal Mines.* John Della Bella, T. Chaloner, and W. Chaloner, all of Preston. Eng. Pat. 15,694, August 27, 1885.

A WEIGHTED bulb carrying an air vessel or balloon at the top of a vertical stem is made to float near the top of a column of water in a suitable vessel. The upward and downward movements of the bulb are intended to give indications of the quantity of "gas" present. Instead of this arrangement, the air balloon may be fixed at one end of an oscillating beam, the other end being provided with a sliding balance weight.—A. R. D.

*A Method and Apparatus for Extracting Nickel and Cobalt from Ores containing them.* Lorentz Albert Groth, London. From Demetry Mindeleff, San Francisco, U.S.A. Eng. Pat. 10,491, September 4, 1885.

THE ore in its rough state is heated to redness in a retort, through which is then passed a current of hydrocarbon gas until a sample of the resulting gases, passed through a solution of a lead or copper salt, gives no black precipitate (indicating absence of hydrogen sulphide, and completion of the reduction). After passing from the retort, the arsenical and sulphuretted gases are water-washed, and returned to the gas-holder. The charge is next cooled in a reducing atmosphere, withdrawn, crushed, and transferred to a wooden tub; here it is kept in constant motion by means of revolving arms, and is submitted to the action of an electro-magnet. This electro-magnet is so actuated by the use of a cam and automatic contact breaker, that it is alternately plunged—the electric circuit being then complete—into the revolving ore, and then subjected to a first vertical and then lateral movement, accompanied by a break of conductive continuity, which thus permits the magnetic particles to fall from the magnet into the receptacle provided for them. In this manner all magnetic metallic particles are gradually removed from the ore tub to the receiving vessel, and may be subsequently treated as desired.—W. G. M.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

*Fat from the Fruit of Myristica Surinamensis.* C. L. Reimer and W. Will. Ber. 18, 2011—2017.

THE fruit of the *myristica surinamensis*, imported into Germany under the name of "oil-nut," has been the subject of a very complete analysis by the authors. The nuts have the size and form of a cherry, with a dark grey brittle shell enclosing a hard kernel. The kernels freed from shell were ground to powder and extracted with ether; 73 per cent. dissolves, and the residue forms a reddish mass, which has not been further examined. The crude fat contains resin and a free acid. The amounts of these were determined by dissolving the crude product in petroleum spirit, which leaves the resin undissolved. The latter amounts to 6.6 per cent. of the crude fat. The petroleum solution was treated with dilute soda solution, and the alkaline liquid separated and acidified, and then extracted with ether. The ethereal solution left a residue of 6.5 per cent.; 100 parts of crude fat contain therefore 57 parts of pure substance. The pure fat has the formula  $C_{45}H_{111}O_6$ , which agrees with that of trimyristin. Like tristearin and tripalmitin, this body exists in different modifications with different melting points. To determine further the composition of the trimyristin, it was saponified with alcoholic potash, by which means an acid of the composition  $C_{15}H_{31}O_2$ , or myristic acid, is formed. No other glycerides exist in this fat. The free acid in the crude fat was found to be myristic acid. Owing to the purity of the fat, and the absence of other glycerides, the author recommends it as a source of pure myristic acid.—J. B. C.

*Detection of Fat Oils in Mineral Oils.* F. Lux. Zeits. Anal. Chem. 1885, 357.

IN cases where the proportion of the former is large (10 per cent.) it suffices to boil the oil (5cc.) for two

minutes with fragments of sodium hydrate. Saponification is indicated by the smell and by the solidification of the liquid on cooling. For the detection of smaller proportions the test must be more carefully carried out. Small quantities are heated both with metallic sodium and sodium hydrate at 200–210° in test tubes placed in a paraffin bath. After heating for fifteen minutes, the tubes are removed and allowed to cool. The presence of a fat oil—i.e., a soap, is indicated by the solidification (gelatinisation) of the contents of one or other, or both tubes.—C. F. C.

*Improvements in the Distillation of Fatty Substances and the like, by means of Superheated Steam and Apparatus therefor.* W. P. Thompson. From M. Julien and M. Rhinowski, Odessa. Eng. Pat. 14,700, November 7, 1884.

A CYLINDRICAL boiler, provided with domes, connected with condensers, is traversed by a long series of pipes for superheated steam, which finally issues into the contents of the boiler by perforations in the last coil. Apparently no external fire is used in the distillation.—W. L. C.

*An Improved Disinfecting Compound and Soap.* John Jeyes. Eng. Pat. 16,427, December 13, 1884.

GAS-TAR is distilled and the light oil rejected; 16 parts of the heavier oil, 32 parts of cocoa-nut oil, and 16 parts caustic soda at 35° Baumé, are saponified in a jacketed pan, with or without the addition of rosin and sodium sulphate and carbonate.—W. L. C.

*An Improved Manufacture of a Detergent.* W. Needham. Eng. Pat. 16,490, December 15, 1884.

SOAP-PASTE, while hot, is mixed with one-half its weight of magnesia mica, a bye-product in the washing of china clay.—W. L. C.

*An Improved Cleansing Compound.* F. J. Harrison. Eng. Pat. 16,547, December 23, 1884.

TWO tons of soap are dissolved in 500 gallons of water; 6 tons of "pure alkali" are added, and water enough to keep the whole at the consistency of cream; with this are mixed 8 cwt. of muriate of ammonia with which has been incorporated 8 gallons of hydrogen peroxide. For the latter, 5 per cent. on the whole bulk, of chloride of soda, is sometimes substituted.—W. L. C.

### XIII.—TANNING, LEATHER, GLUE, AND SIZE.

*Process for Purifying Vegetable Tannin Extracts.* Jules Douteleau. Eng. Pat. 14,561, November 4, 1884.

THE process consists in boiling the extract with a sulphite, or hyposulphite, preferably the hyposulphite of alumina. A suitable proportion is 1 grammic per litre of extract of 2° B.—H. R. P.

*Manufacture of Artificial Leather.* Communication from H. Schwabacher, of Paris. Eng. Pat. 14,587, November 4, 1884.

A COTTON fabric is treated with a mixture of 5 parts of decoction of linseed, 4 parts of rabbit-skin glue, 1 part of boiled linseed oil, and a sufficiency of colouring matter. It is then dried on a polished zinc plate heated by steam.—H. R. P.

*Improvements in Aluming or Curing Hides or Skins.* Bertram Hunt. Eng. Pat. 15,607, November 27, 1884.

INSTEAD of using alum and salt, as is customary, the patentee employs a solution of a basic aluminic salt, prepared by adding sodic carbonate to a solution of alum, or aluminic sulphate, or chloride, or by dissolving freshly precipitated aluminic hydrate in it. A small quantity of salt is in some cases used. The use of basic salts of other metals is also claimed.—H. R. P.

*Apparatus for Steeping, Lining, Baiting and Tanning Hides.* Chas. Louis Royer. Eng. Pat. 15,527, December 2, 1884.

A VAT is provided with a vertical axis and radiating arms, to which the hides are attached. It is practically identical with the ordinary German Dreh-kalk.—H. R. P.

*Improvements in the Production of Tanning and Dyeing Materials.* Thos. Cobley. Eng. Pat. 408, January 18, 1885.

OAK-LEAVES, twigs, and other forest refuse, are put up in a horse-cutting machine, and exhausted to form a fluid extract; or dried, ground, and sifted, to form "oak-leaf sumac."—H. R. P.

*Improvements in Artificial Leather.* E. M. Freeley. Eng. Pat. 2158, February 17, 1885.

LEATHERETTE or rubber-cloth is treated with tanning infusions, and scented with Russian birch-oil (*juchten*) extract.—H. R. P.

*An Improved Process for the Manufacture of Glazed Leather.* Thos. R. Clark. Eng. Pat. 7915, June 30, 1885.

INSTEAD of tawing the skins with alum, salt, egg yolk, and flour, the skins are tawed or chamoised with oil. The oil is very carefully removed by repeated treatment with naphtha or mineral volatile oil, when the skins may be dyed and glazed in the usual way.—H. R. P.

### XV.—SUGAR, GUMS, STARCHES, Etc.

*Specific Rotation of Invert Sugar.* O. Gubbe. Ber. 18, 2207–2219.

THE specific rotation of a solution of invert sugar depends not only upon the concentration and temperature, but also upon the nature and proportion of acid used for the inversion. In this paper experiments are detailed with a view of determining the effects produced by these several causes.

[I.] *Influence of Acid.*—In the case of sulphuric and hydrochloric acids, the specific rotation increases with proportion of the acid in accordance with the formula 
$$[\alpha]_D^{20} = - (19.983 + 16979x)H_2SO_4 \text{ or } - (19.995 + 3261x)HCl$$
 in which  $x$  is the proportion of acid to 10 parts invert sugar and 100 parts water, whereas the specific rotation is independent of the proportion of oxalic acid, which was accordingly used for the experiments described below.

[II.] *Influence of Concentration.*—From the experiments the following formula is deduced for solutions at 20° containing less than 35 per cent. sugar:—

$$[\alpha]_D^{20} = -23.305 + 0.01612c + .0002239c^2;$$

beyond this degree of concentration, secondary decompositions, such as caramelisation, ensue, so that the curve expressing the specific rotation in terms of concentration is irregular.

[III.] *Influence of Temperature.*—The general formula deduced is 
$$[\alpha]_D = a + bt + ct^2,$$
 in which the constant  $a$  only is dependent upon the concentration,  $b$  and  $c$  on temperature. For solution at 0° to 30° C. the formula holds good:—
$$[\alpha]_D^{t-20} = -23.305 + 30406(t-20) + .001654(t-20)^2,$$
 and between 20° and 100°

$$[\alpha]_D^{t-20} = -23.305 + 32464(t-20) - .0002105(t-20)^2.$$

The above results indicate that Clergel's formula for the determination of crude sugar by inversion is not exact, since there is not the simple proportionality between the differences of angle of rotation before and after inversion ( $D$ ), and the quantity of sugar in 100cc. (3), as expressed by the formula  $D = Az^2$ , but rather on  $D^2$

account of the variation of specific rotation with concentration, the following formula is preferable,  $D = Az + bz^2$ . Thus, if 19 grm. of the sugar to be examined are dissolved in 100 cc., the percentage,  $x$ , of pure sugar, can be calculated by means of the equation

$$D = 1\frac{3}{5}ax + (\frac{1}{10})^2bx^2 \text{ and } D = 33143x + 000023x^2 \\ (c = \frac{1}{10}ax)$$

an actual example is given of the application of these formulae.—V. H. V.

*Detection of Cane in Milk Sugar.* Lorin. Pharm. Zeit. für Rußland. 17, 372.

A MIXTURE of equal parts of milk sugar and oxalic acid melts when warmed upon the water bath, and becomes very faintly darker in tint. An addition of one per cent. of cane sugar causes the rapid development of a dark tint on heating, and with several per cent., the mass is rendered greenish-brown or black by this treatment. The serviceableness of this test is confirmed by Geissler. (Pharm. Cent. 1885, 244.)—W. D. B.

*Improvement in the Method of and Apparatus for Boiling Sugar.* F. B. Welch, Manchester. Eng. Pat. 500, January 14, 1885.

THE juice, which maybe evaporated in an open pan or a vacuum pan, is kept constantly agitated, either by a mechanical contrivance, such as revolving blades or stirrers, or by the action of air passing through the juice.—A. J. K.

*Process for the Purification and Decoloration of Saccharine Liquors, Juices, or Syrups.* C. D. Abel. From La Société Nouvelle de Raffineries de Sucre de St. Louis-Marseilles. Eng. Pat. 2724, February 28, 1885.

OXIDES or salts of tin are applied in any of the following ways: (a) Introducing into the liquid stannous or stannic oxides previously prepared, boiling the mixture for some minutes and filtering; (b) introducing a salt of tin (stannous sulphate) along with a base, such as baryta (or barium carbonate), boiling for some minutes and filtering from the oxide of tin and the barium sulphate; (c) adding a salt of tin, boiling, neutralising the acid liberated from the salt by a base like lime, and filtering; (d) adding first a salt of an alkali or alkaline earth (such as  $\text{BaCO}_3$ ), heating to boiling, and then adding a solution of a salt of tin in small successive quantities, and filtering.—W. S.

*Improvements in the Manufacture of Starch Meal.* W. R. Lake. From W. T. Jebb, U.S.A. Eng. Pat. 4954, April 21, 1885.

A KERNEL of Indian corn or maize consists of three principal parts—viz., the inner portion or body, which consists principally of starch cells; the outer enclosing skin or hull and its glutinous lining, which consist of wood fibre, nitrogenous compounds, albumen and oil, which are useful for cattle feed; and the germ, which is located at the small or cob-end of the kernel, and is very rich in oil, the latter forming about 70 per cent. of its constituent parts. To obtain the crude starch from the Indian corn various processes have hitherto been used—the wet “sour or fermentation” process, the wet “sweet” process, and sundry dry processes. These are described by the author, and the several objections to them are pointed out, such as the length of time, and large amount of water required, difficulty of obtaining a complete separation of the hull, gluten and oily germs from the starch, etc. The object of the present invention is to overcome these difficulties, and the process adopted is as follows:—

The maize is first steeped in a suitable tank at about 140° F. for about 15 hours. At the end of this time it is found that the starchy body of each kernel has become enlarged and soft, the germ has also swelled, and the hull become tough, and the three portions exhibit a tendency to separate from each other. Care must be taken that the temperature of the maize does not rise to 155° F., or

the starch grains will burst, and render any subsequent separation difficult, if not impossible.

In order to effect the desired separation, cold water is first introduced into the steeping tank to cool down the mass, and when this is effected the water is drained off. When thoroughly drained, the maize is next subjected to the action of a reducing machine consisting, preferably, of several concentric rows of beaters or whippers revolving at high speed in opposite directions within an enclosing case. On emerging from here, the maize is found to consist of a mixture of finely pulverised starch, of entire oily germs, and of the husks which have been torn off in the form of large flakes; and the whole, moreover, is now in a sufficiently dry condition to enable the further separation to be proceeded with. This is effected by passing the “reduced” material over a vibrating screen. The upper portion of this screen consists of fine wire-gauze through which the finely-powdered starch passes, the lower portion of a coarser material through which pass the germs, whilst the hulls escape over the end. Each portion is collected in a separate receiver. The starch meal thus obtained may be further reduced by grinding in a “Bogardus” or other mill, and applied to the purpose for which it is required.—A. J. K.

*Improved Starch Meal.* W. R. Lake. From W. T. Jebb, U.S.A. Eng. Pat. 4948, April 21, 1885.

THIS patent appears to have been taken out to protect the starch meal, which is the product of the process described by the same author. (Eng. Pat. 4954.) See above.—A. J. K.

*Improvements in the Manufacture of Starch.* W. R. Lake. From W. T. Jebb, U.S.A. Eng. Pat. 6139, May 19, 1885.

THIS patent is supplementary to the one described above (Eng. Pat. 4954), and has reference to the further treatment of the starch meal as it is obtained from the screen described therein. To obtain this meal in a finer state of division, and to free it from any remaining trace of fibrous matter or oil, it is treated as follows:—The meal is ground in a mill with water which passes from a pipe between the grinding surfaces of the mill. A separating sieve, covered with bolting cloth, receives the wet ground meal, and is provided with perforated pipes which, delivering fine sprays of water over the cloth, carry through the finely-ground starch, and work off the oil at the tail of the vibrating sieve. The water and starch are received into large settling tanks from which, when the starch has settled, the water is run off. The starch may now be dried and packed, or may first be further purified by repeated washing, either by pure water or very weak caustic soda solution. By this means a very pure fine starch meal may be obtained.—A. J. K.

*Improvements in the Manufacture of Refined Sugar and Apparatus therefor.* Peter Jensen. From M. C. P. Barbe, Amsterdam. Eng. Pat. 10,172, August 27, 1885.

BY the method described in this patent, the various processes necessary for the production of pure lump sugar from the “masse cuite” are conducted in rapid succession in one apparatus. This latter consists of a specially constructed centrifugal machine for the details of the construction of which reference must be made to the specification itself.—A. J. K.

## XVII.—CHEMISTRY OF FOODS. SANITARY CHEMISTRY, DISINFECTANTS, Etc.

### (A) CHEMISTRY OF FOODS.

*Depeptonisation and Theory of Digestion.* T. Chandelson. Ber. 18, 1999—2011.

IN a former paper (Ber. 17, 2144) the author has observed the conversion of albumen into peptone by the action of hydrogen peroxide. The analogy of this reaction to

that induced in the process of digestion by peptic ferments lends support to either of the following hypotheses:—(1) The action of the ferment consists in the intermediate formation of hydrogen peroxide, or (2) that their constitution is similar to this compound. By a series of comparative experiments, the former hypothesis is shown to be incorrect; as regards the second, it is demonstrated that hydrogen peroxide can restore to activity pepsin rendered passive by sodium carbonate, whereas dissolved oxygen does not possess this property. It would thus appear that there exists in pepsin ferments a substance of the nature of a peroxide, which transforms albumen, or rather syntonin, into syntonipepsin with or without peptone; and, secondly, that dilute acids react on the syntonipepsin to produce a molecule of peptone, and a molecule of an intermediate substance, *zymogen*, which gives oxygen to reform pepsin. The substance *zymogen* is produced when peptonisation ceases, from the presence of too large an excess of fibrin; it is insoluble in glycerol, but by the action of acidified water is converted into peptone and pepsin. It is probably identical with the *insoluble pepsin* of Gaultier (*Compt. Rend.* 94, 582) and the pepsinogen of Elstner and Gentner (*Ibid.* 652 and 1192).—V. H. V.

### (B) SANITARY CHEMISTRY.

*Dissolved Oxygen in Well-Waters.* B. Lepsius. Ber. 18, 2487—2490.

IN the choice of a water supply—especially in the case of well-waters—attention should be paid to the quantity of dissolved oxygen, and the rate at which this varies with the depth. The Berlin water supply, obtained from the Tegeler Lake, has proved to contain a dangerously large quantity of iron; and Finkener, in his investigation of this matter, has shown that the solution of iron proceeds with great ease whenever the quantity of dissolved oxygen in the water is diminished by gradual processes of oxidation; the percentage of  $\text{CO}_2$  meanwhile increasing. According to Bunsen, water at  $10^\circ$ , which has been shaken up for some time with air, contains 12.7 cc. nitrogen and 6.8 cc. oxygen per litre, or 34.8 per cent. of oxygen, calculated with reference to the total of oxygen and nitrogen. In well-water, from wells sunk near the Tegeler Lake, Finkener found 10.91 cc. nitrogen to 1.75 cc. of oxygen, or only 13.8 per cent. of the latter, whereas the water of the Tegeler Lake itself contains 29.5 per cent. of oxygen; so that by gradual filtration into deeper strata, the percentage of oxygen is reduced from 29.5 to 13.8. That water readily loses its oxygen when placed in contact with organic matter, has been proved by Reichard, who has examined the action of turf upon rain-water. In five hours the water loses four-fifths of its oxygen, and after 48 hours only traces are left. Miller found that the dissolved oxygen and nitrogen in the Thames water above London (at Kingston) were in the proportion of 1 to 2, whereas below London (at Woolwich) the ratio was 1 to 52. Well-water is generally obtained from sandy strata, which contain more or less iron; and in deep wells the gradual absorption of oxygen can be recognised by examining samples of the water. Those from the upper strata are yellowish-red in colour; as the depth increases, and the iron changes from the ferric to the ferrous state, the colour becomes darker. If the water contains dissolved carbonic acid, then, in passing through the lower strata, the iron goes into solution, provided that there is not sufficient oxygen present to decompose the ferrous carbonate again into carbonic acid and ferric oxide. This is the reaction which occurs when ferruginous water is exposed to air, the water itself becoming yellow and dirty. It is evident that the extent to which the iron is dissolved will depend upon the quantity of organic matters undergoing oxidation, and upon the amount of dissolved oxygen; hence the importance of determining the latter constituent. In the presence of gypsum, another injurious effect may be produced: for if the water contain no oxygen, then the gypsum is reduced, by the oxidation of organic matter, to calcium sulphide, so that the water, on exposure to air, evolves sulphuretted

hydrogen. In examining the Frankfort well-water, the writer had to take samples from bore-holes of only 8.15 cm. diameter; the apparatus shown in the figure was found very convenient. It consists of an iron frame, the upper part of which supports an inverted flask *a* of 30 cc. capacity, filled with mercury; through the india-rubber stopper pass the bent tubes *b* and *c*, which are also filled with mercury; *c* is drawn out to a capillary end, bent round, and a loose string *f* tied round it. The lower disc

carries the vessel *c*, and the whole apparatus is suspended by wires to the rope *d*. When it has sunk to the bottom of the bore-hole, the capillary point of *c* is broken off by pulling the thread *f*; the mercury flows into *c*, and is replaced by water flowing in through the tube *b*. The sample can thus be obtained without coming into contact with air, or with other water. It can be boiled in the same flask, and the gases determined as usual by Bunsen's method. The water was examined at depths of 12, 18, and 25 metres. At 12 metres, the percentage of oxygen was 24, at 18 metres, 22; but in passing from 18 to 25 metres the percentage fell to 13, and the water taken from the latter depth gave a slight yellow precipitate on standing in air.—D. E. J.

*On the Influence of Industrial Processes on the Composition of River Water.* Richard Caspari. Staatslehranstalt zu Chemnitz, 1884.

THE first ten pages of this monograph consist of an interesting resumé of the general and historical aspects of the subject, special reference being made to the work and reports of the Rivers' Pollution Commissioners of 1865 and 1868. In spite of the mass of statistical matter collected by the said Commission, it could not be definitely stated that the fouled streams had a direct injurious influence on health, as it appears that the death-rate is subject to the action of so many other factors. In 1877, a map was prepared in Saxony, showing the

localities of 273 cases of gross river pollution, and accompanied by an explanatory text. It appears that establishments of the textile industry are by far the worst offenders in this respect, and in the first of these are specially named dye-works, bleach works, and woollen mills. In addition to the above, the following table shows percentages of cases in each trade calculated on the total number:—

Paper trade .....	9
Leather trade .....	8
Mining .....	8
Preparation of foods, liquors, etc. ....	6
Illuminants, etc. ....	4
Manufacture of clothing, and cleansing the same .....	2
Chemical trades .....	2
Metal trades .....	1
Wood, etc. ....	0.3
Sewers of towns, etc. ....	7

The author then proceeds to discuss separately chemical means of purification, filtration, and irrigation. Of chemical methods are mentioned treatment with lime, Stüvern's mixture (caustic lime, coal-tar, and magnesium chloride), and Sillar's A.B.C. mixture. Also several others of minor importance. With respect to the filtration method, it appears from the R.P. Commission report that good results are obtained if in 24 hours a maximum of 33 litres of water comes into contact with each cubic metre of filtering mass. Consequently this plan entails large and costly plant and settling tanks, but is to be recommended for smaller quantities. Recently a large number of filtering arrangements have been devised and patented; amongst others being H. Petri's method (D.R.P. 19,698, November 10, 1881) of covering the actual filter with a layer of turf treated with creosote. Irrigation methods give an intermittent filtration of the very best kind. Not only is suspended matter removed, but the substances in actual solution are chemically altered. Irrigation experiments at Norwood, Croydon, Aldershot, and various towns on the continent are briefly discussed. Irrigation, besides for liquid and solid faecal matter, is specially suitable for treating the waters from dyeworks, tanneries, soap works, sugar mills, woollen mills, etc. This plan would be much more extensively used if the required ground were always at disposal. The following industries are then discussed more minutely in the combination given below:—

- (a) Bleach, dye and print works.
- (b) Woollen and cloth mills.
- (c) Paper mills, mechanical pulp mills, straw board and cellulose works.
- (d) The utilisation of ammoniacal liquors from gas works.
- (e) Breweries, distilleries, sugar mills, and tanneries.

(a) From the works in this section very large volumes have usually to be dealt with. In addition to strong dyes and the chemicals employed in the baths, we have here to do with exhausted dye-woods, plant residues, cow-dung, fibres, etc. The chief point to be attended to is the removal of suspended matter as far as possible, seeing that the dissolved matter is usually much diffused in large volumes of water. If the lime treatment be employed, the tanks for settling should be as large as possible, and arrangements made for causing the water to travel as long a distance as practicable before being run out of the said tank or reservoir. The large dye-works would do well if they were to treat the spent water from the rinsing baths a perfect or efficient treatment becomes almost impossible. The more concentrated waters, the easier they are to precipitate and clear by means of lime. The lime process has been objected to as not attaining the desired end. This may be true with excrementitious matter, but for dyeworks, etc., it is by far the best and cheapest plan. Acids and colouring matters are combined, metallic oxides from mordants, albuminous and other matter liable to putrefactive change is precipitated in an insoluble form. The problem of rendering harmless the waters from dyeworks, etc., has been well solved by Messrs. W. Spindler, of Berlin. They mix their spent baths, the contents of

urinals and closets, and waste waters generally, after settling out, with lime and magnesium chloride, and then employed irrigation. A full description with analyses at various stages is given. Some idea may be given of the quantities of soluble matters introduced into river waters by dyeworks, etc., when it is stated that analysis of the water from a certain cotton dyeworks showed a solid residue of 1.516 grms. per litre. Bleach-works usually turn out alkaline and soapy liquids containing small quantities of free acid and chlorine with calcium chloride and calcium sulphate. Large quantities of froth are also met with. As the organic matters are mostly fat acid salts of alkalis, sizing mixtures and suspended fibres, the dark leys are mixed with the soap-water, settled out, mixed with the waste bleach liquors, settled again, and then run off diluted with large quantities of rinsing waters.

(b) Wool and cloth mills should be subjected to severe control, especially as progress has been made in the profitable utilisation of the waste products resulting. The following are analyses of wool by Faist:—

	(a)	(b)
Mineral matter .....	6.3	16.8
Fatty matter ("suint" etc.) .....	41.3	11.7
Pure wool fibre .....	35.0	28.5
Moisture .....	11.4	7.0

Chevreul has shown that "suint" contains the potash salt of a fatty acid. Reich and Ulbricht found oleates, stearates, probably palmitates; and according to E. Schulze benzoic acid and cholesterol are never missing. In some mills the waste wash-waters are concentrated to a syrup and then distilled for gas with ammonia, tar and potash as by-products. E. Schwannborn, in Aachen, has introduced a lime process into actual practice, which gives good results. The lime soap obtained is mixed with coal and worked for gas. The cloth mills at Daleran, near Lennep, use a modification of Schwannborn's process, and work their lime soap for fat. It is stated that the wash-waters produced yearly in Europe correspond to 2,000,000 cwt. lime soap. Various other patented processes are then described.

(c) Paper-mills and allied establishments have a great influence from a sanitary point of view. We have here to deal with the leys from boilers, the washings from the various classes of rag-engines, back-water, residues from bleaching powder, etc. In addition to soda, lime, china-clay, and many other mineral matters, we meet with large quantities of putrescible organic matter causing discolouration, froth, and the death of fish. The ley from the rag-boilers is muddy, alkaline, and soon gives off  $\text{SH}_2$ . That from straw is clear, dark-brown, and slightly alkaline. Analyses are given. If the two are united in a water-course, a very large amount of contamination results. Esparto liquors are still worse, and have been found to contain as much as 938.845 parts of organic carbon, and 77.042 parts of organic nitrogen per 100,000. In some cases, owing to the large amount of soda in these liquors, regeneration does away with them in a profitable manner (as much as 80 per cent. of the  $\text{Na}_2\text{O}$  used can often be recovered.—Abstractor).

The recovery of fibres from the waste waters does not cause much trouble when "save-alls" are used. The waste-waters from mechanical pulp mills, from soda-pulp mills, and from sulphite cellulose manufactories, are also considered separately. The waste-water from wood-steaming works is rather of an antiseptic nature.

(d) Gas-waters are those derived from the condensing and scrubbing arrangements, and are always mixed. These are now mostly worked up for valuable products. In examining a water-course for contamination from gas-works, the chief to look for is the presence of the salts of the lower sulphur acids, which are characteristic. Empyrenatic matter and sulphide of ammonia are often retained by the earth; the smell of the tar would then of course be absent. Nitrous acid is also of importance.

(e) The waste-waters from breweries vary in composition according to the cereals employed. More or less gummy matter, sugar, soluble legumin and plant fibre are always present; also potash, lime, magnesia, silicic acid, sulphuric and phosphoric acids.

In the wash-waters from barley, succinic acid has also been found. Special attention must be paid to these

waters in summer time, when they greatly favour the formation and development of one of the algae—viz., *Leptothrix luteus*.

The lime process is found to answer very well in this and similar cases. Also in certain cases Süvern's mixture. The precipitate being rich in nitrogen and phosphoric acid, can be used as manure.

The waters from distilleries can be similarly treated with advantage. Here we have liquors at a high temperature containing much putrescible organic matter, also fusel oil, amyl alcohol, acetic and valerician acids.

Great dangers are attached to contamination from "vinasse" liquors containing undecomposed starch, dextrine, peptone, proteids, fat, small quantities of maltose and dextrose, salts, yeast, glycerine, etc.

Camille Vincent's process has been a signal success, allowing, as it does, of the disposal to considerable advantage of these dangerous liquors.

Sugar works are also serious offenders, likewise tanneries. Causes and cure are discussed.—H. A. R.

## XVIII.—ELECTRO-CHEMISTRY.

*Improvements in Galvanic Batteries.* A. Schanschiff, Gipsy Hill, Surrey. Eng. Pat. 16,375, Dec. 12, 1884.

THE positive and negative elements of a battery are made in the form of discs, and are mounted upon an axis made of insulating material; the axis of the discs is placed upon bearings above the top of a trough, partitioned off into cells, into which the lower part of the discs dip, so that one half of each disc will be exposed to the atmosphere, and the other half will dip into the liquid in the trough. When the battery is in action, a slow revolving motion is given to the axis, either by means of a small dynamo-electric engine, which receives a portion of the battery current, or by a small water-wheel, or by other convenient means.—T.

*An Improved Apparatus and Process for the Electrolytical Separation and Deposition of Metals.* A. M. Clark. From Bernhard Meibius, Chihuahua, Mexico. Eng. Pat. 16,554, December 16, 1884.

THIS patent consists of sixteen claims, and relates to a process and apparatus for refining silver and separating it from gold, platinum, copper, lead, and other metals by means of electricity, which apparatus when slightly modified can be used in other electrolytical processes for the decomposition and precipitation of metals by electricity.—T.

*Improvements in Secondary Batteries.* W. H. Akester and R. Mitchell, Walham Green, and R. R. Kelly, Queen Victoria Street. Eng. Pat. 1221, Jan. 28, 1885.

THE object of this invention is to so construct the cells of a lead secondary battery, as that the acting agents required for any given capacity of storage will be concentrated in a considerably less space, and will be disposed in a far more advantageous and effective manner than in any accumulator or secondary battery as formerly constructed, and which will consequently permit of any given amount of electric energy being stored in a battery occupying considerably less space, and weighing very much less than any existing secondary battery capable of storing and effectually utilising a like amount of electric energy.—T.

*Improvements in and relating to Electric Batteries.* W. R. Lake. From H. L. Brevoort and J. L. Roberts, both of Brooklyn, New York. Eng. Pat. 1505, February 3, 1885.

IN order to prevent polarisation in electric batteries having zinc and carbon elements, the author proposes to use solutions of permanganate of potash and bichromate of potash, instead of a solution of sal-ammoniac, which is generally used. Under this patent is included a novel connection of a metal conductor to a carbon element by means of a conductive metal or metallic alloy applied in

a molten state, and being of such a character that it will expand on cooling, so as to secure the carbon element and conductor together.—T.

## XIX.—PAPER, PASTEBOARD, Etc.

*On the Moisture contained in Materials for Paper Manufacture.* B. Lepsius. Ber. 18, 2491—2492.

THE price of these materials (prepared from wood) is generally based upon the weight of the "air-dried" substance; but as this term is somewhat indefinite, an average sample is usually taken, dried by heating for a considerable time to 100°, and twelve per cent. moisture added to the weight of the dry substance thus determined. The following observations were made in order to test the correctness of this method, and the results show that the percentage which should be added varies according as the materials have been prepared by chemical means or by mechanical processes alone. The materials were examined in the state in which they came from the machine; the samples were allowed to remain in a room at a constant temperature of 20° until the weight became constant, the amount of moisture present being determined by a hygrometer, and maintained constant at fifty-five per cent. relative humidity. All determinations of "air-dried weights" were made under these normal conditions, for preliminary experiments showed that changes in temperature or humidity produced considerable variations in weight. The samples were then dried at 100°, and quickly weighed; a comparison of both weighings gave the amount which should be added to the latter. In the case of materials prepared by mechanical means from aspen wood (white) and deal (white and brown) the usual methods were found correct; but the so-called celluloses, prepared from wood and straw, by the soda and bisulphite processes (both bleached and unbleached), required the addition of only ten per cent. to the weight of the substance dried at 100°.—D. E. J.

*Improvements in Manufacture of Materials for Making Artificial Ivory, etc.* T. F. Best, Middlesex. Eng. Pat. 15,121, November 18, 1884.

IT is proposed to manufacture an improved substitute for ivory, horn, coral, amber, malachite, whalebone, gutta-percha, etc. Cellulose matter is first treated in the usual manner with a mixture of  $\text{H}_2\text{SO}_4$  and  $\text{HNO}_3$ , and the excess of acid neutralised by heating the mass with a solution of  $\text{SO}_2$ , preferably in a closed vessel and to about 100° F. Pressure is employed to remove the acid solution, and then 10–50 gallons of water are added to every 50lb. weight of mass. Washing then follows, to remove all traces of soluble acids, and then bleaching, if required. Crude camphor is dissolved in about its own weight of methylated spirit, or methylated spirit and liquid hydrocarbon mixed, passed through a percolator charged with any suitable drying agent, and decolourised by the use of charcoal. To every 50lb. of cellulose treated as above, inventor adds 55 to 60lb. of the above solvent to form a plastic mass. The mass can be coloured, if required, and for decreasing the inflammability of the mass 12.5 to 25 per cent. of borate of magnesium is added.—H. A. R.

*Improvements in the Treatment of Paper and other Fibrous Materials for the Production of a New Material and of Articles therefrom.* H. W. Morrow, Wilmington, U.S.A. Eng. Pat. 9319, Aug. 4, 1885.

PAPER is converted into a pasty substance by the action of  $\text{HNO}_3$ , or the nitrates of zinc or lime. Other acids, bases, salts or solvents of cellulose may be added to the bath, as may also cupra-ammonium, zinc-ammonium, or chloride of zinc. If nitric acid be used alone, inventor prefers a strength of 42–49° Bé. If nitrates be used, 55–75° Bé. is prescribed. Sized or unsized sheet paper may be treated to produce (a) tough and strong texture, high polish, non-inflammability, and

resistance to acids and alkalis; (b) softness and flexibility. Sheets may be cemented together to form slabs or rolls, if required. The sheet or slab is then soaked in alkaline or clear water, according to the character of the product required, and may receive a coat of gum, oil, albumen, glycerine, saccharine matter, or any mixture of the same. Compound sheets may be made by the interposition of woven materials between the sheets. Starch, gum, mucilage, dextrine, albumen, or any form of cellulose may be advantageously introduced in addition, either with the paper or with the fabrics; also, if desired, earthy and mineral matters. Softening, etc., may be done by the use of glycerine baths, etc.—*e.g.*, two-thirds water, and the remainder glycerine or glycerine and saccharine matter combined. Patentee, however, prefers to accomplish this by means of deliquescent salts introduced into the substance of the material, to which he gives the name of "celluvert." The following are some of the uses to which inventor proposes to put the new material: Lining cans, pump valves, plate glazing strips, tubes, gibs for engine cross-heads, friction gears, gaskets, sounding boards, washers, acoustic aids, non-conductors of electricity, etc., etc.

—H. A. R.

*Improvements in Waterproofing Paper and other Materials.* W. Macrone, Glasgow. Eng. Pat. 9411, August 7, 1885.

INVENTOR carries the paper to be waterproofed in a web through a tank of size, heated to  $212^{\circ}$  F. at a sufficiently slow rate. After passing suitable arrangements for removing the surplus, the paper receives a coating of powdered stearite, the excess being brushed off. The size or varnish to be employed forms the subject of another patent deposited at the same time.—H. A. R.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*Commercial Cocaine.* W. Merck. Ber. 18, 2264—2266.

THE author recently pointed out the existence of an alkaloid, benzoyl-ecgonine, in commercial cocaine. He has now succeeded, by introducing a methyl group into this compound, in converting it into cocaine. An attempt was first made by heating the compound with methyl iodide and caustic potash in sealed tubes at  $100^{\circ}$ , but the benzoyl-ecgonine was decomposed with formation of methyl benzoate and methyl alcohol. By employing a slight excess of methyl iodide, an equal volume of methyl alcohol, but no caustic potash, the hydriodide of cocaine was formed. The methyl iodide and methyl alcohol were removed by distillation, and the syrupy residue treated with water, when the hydriodide slowly crystallised. The aqueous solution was treated with moist silver oxide, and filtered. The residue was washed with cold water to remove unaltered benzoyl-ecgonine, and the cocaine dissolved in hot alcohol. After recrystallisation from alcohol it melted at  $98^{\circ}$ , and the alkaloid, and its platinum double salt, were analysed.—S. Y.

*On Some Derivatives of Methylhydroquinoline.* Adolf Feer and Wilhelm Koenigs. Ber. 18, 2388—2393.

QUINOLINE methyl iodide was dissolved in ten times the quantity of concentrated hydrochloric acid, and treated on the water bath with  $\frac{1}{2}$  parts of granulated tin. A red tin double salt separated, became white, and was finally redissolved. The solution was concentrated, made alkaline with strong caustic soda, and steam-distilled. The distillate was shaken with ether, and the ethereal solution dried with potash. After removal of the ether by distillation, the residue was fractionated. The greater part of the kairoline distilled over between  $242^{\circ}$  and  $244^{\circ}$ , and nearly half the calculated amount was obtained. Methylhydroquinoline or kairoline resembles dimethylaniline in its behaviour with nitrous and nitric acids, and with benzenyl trichloride, whence the authors conclude that in the nitroso and nitro compounds, a hydrogen atom of the benzene ring, in the para-position with regard to the nitrogen, is replaced.

*Nitrosokairoline*,  $C_{10}H_{12}N.NO$ . A solution of kairoline in 50 parts of very dilute sulphuric acid was treated gradually at  $0^{\circ}$  C. with the calculated quantity of sodium nitrite. The yellowish-red solution was neutralised with soda, and agitated with ether. The residue, after evaporation, was recrystallised from petroleum spirit, animal charcoal having been added to the solution. After further purification, the compound crystallised in green scales, resembling nitroso-*o*-dimethylaniline. It dissolves readily in alcohol, ether and benzene; less easily in petroleum spirit. It has no definite melting point. The composition was confirmed by analysis. Nitrosokairoline does not give Liebermann's reaction, nor is it decomposed in the same manner as nitroso-dimethylaniline, by boiling with caustic soda.

*Nitrokairoline*,  $C_{10}H_{12}N.NO_2$ . Kairoline was dissolved in 10 parts of concentrated sulphuric acid, and treated drop by drop at  $0^{\circ}$  C. with the calculated quantity of potassium nitrate dissolved in strong sulphuric acid. The product was poured into water, and neutralised with caustic soda, when nitrokairoline was deposited in red crystals. After purification of the alcoholic solution with animal charcoal, the compound crystallised in red needles, melting at  $93$ – $94^{\circ}$ . It dissolves in the ordinary solvents, and possesses basic properties like kairoline. It is unaltered by solution in strong acids and subsequent precipitation by water. The body was analysed.

*Dinitrokairoline*,  $C_{10}H_{10}N(NO_2)_2$ . A solution of kairoline in glacial acetic acid was treated at the ordinary temperature with the calculated quantity of fuming nitric acid, diluted with five parts of acetic acid. A portion of the dinitrokairoline was deposited, the remainder was obtained by addition of water, neutralisation with caustic soda, and agitation with ether. The dinitro compound crystallises from alcohol in yellow scales, melting at  $148^{\circ}$ . The composition was proved by analysis. It is not decomposed by strong acids.

*Amidokairoline*,  $C_{10}H_{12}N.NH_2$ , was prepared by reduction of the nitro-compound, dissolved in concentrated hydrochloric acid, by means of stannous chloride. The solution was neutralised with caustic soda, and extracted with ether. A yellow oil was obtained, which crystallised at a low temperature. The platinum double salt was found to have the composition  $(C_{10}H_{12}N_2.2HCl) Pt Cl_2$ .

By the action of sodium nitrite on a solution of amidokairoline in 10 per cent. sulphuric acid, cooled by a freezing mixture, red needles of the sulphate of a base were obtained, which, when heated, evolved no nitrogen, but crystallised out again on cooling. By the addition of caustic soda to a strong aqueous solution of the sulphate, violet crystals, having the composition  $C_{10}H_{13}N_3O + 5H_2O$ , were obtained. This body melts and decomposes at  $144^{\circ}$ . It does not give Liebermann's reaction. The hydrochloride, dried at  $140^{\circ}$ , has the composition  $C_{10}H_{13}N_3O.HCl$ . The oxygen in the free base does not, therefore, exist as hydroxyl.

*Dimethylhydroquinolinium hydroxide.* Tetrahydroquinoline was warmed with excess of methyl iodide on the water bath. After evaporation of the methyl iodide, the solution was shaken repeatedly with ether, and hydrolysed to remove unaltered tetrahydroquinoline and kairoline. The hydroxide was obtained by conversion of the iodide into the ferrocyanide, decomposition with copper sulphate, and precipitation of sulphuric acid with barium hydrate. The concentrated aqueous solution was heated to  $150^{\circ}$ , in an oil-bath. Water distilled over at first, later on, oil, which was driven over completely by passing steam into the residue. The oil was found to be kairoline. The decomposition of dimethylhydroquinolinium hydroxide differs, therefore, entirely from that of the corresponding pyridine compounds, which form trimethylaniline and unsaturated hydrocarbons.—S. Y.

*Vogel's Test for Quinine.* A. Vogel. Sitzungsber. d. Akad. d. Wissensch. München, 1885, 1.

THE author has modified his original test for quinine, which consists in mixing bromine water, yellow prussiate of potash, and borax, to a solution of quinine, by substituting a weak alkaline compound, as for example, marble, felspar, or powdered glass, for borax. When to

a mixture of bromine water, ferrocyanide of potassium, and sulphate of quinine, a small piece of marble is added, the latter is at once covered with a red film. Strycline, cinchonine, and caffeine do not give similar reactions. If a solution of morphine be boiled with excess of bromine water, neutralised with  $\text{CaCO}_3$ , and again boiled, a red coloration is produced, even when diluted to 1 in 1200. When more dilute, a yellow or brown coloration is obtained. If a weak HCl solution of narcotine be treated with a small excess of bromine water, and neutralised with calcium carbonate, the liquid becomes red. When the solution contains more than 1 in 1000, the red colour changes to violet and blue. The coloration is weaker in presence of tartaric or acetic acids. In testing quinine in bark, the tannin present must be first eliminated with gelatine solution, containing  $\text{NiCl}_2$ .

—J. B. C.

## XXI.—EXPLOSIVES, MATCHES, Etc.

*An Improved Combustible Composition to be employed in the Manufacture of Cigar Lights or Fuses.* G. A. Sweetser, Kennington. Eng. Pat. 13,109, October 2, 1884.

THE object of this invention is to provide a light which shall burn down without spluttering, and shall also continue to glow for some time after it has burned down. The heads are composed of a mixture of two parts of powdered charcoal with one of chlorate of potash, and a sufficiency of gum water, or other adhesive liquid. The heads are tipped by an ordinary dipping process, with any suitable igniting composition.—W. D. B.

*Improvements in the Manufacture of Gunpowder.* R. W. S. Griffith, Lyndhurst. Eng. Pat. 11,808, August 30, 1884.

THIS invention relates to improvements in the manufacture of the so-called Schultze wood or sawdust gunpowder, and what is claimed is: firstly, the granulation of a moistened mechanical mixture of nitro-lignin and nitrates, by passing the same through sieves and through revolving barrels or drums; secondly, the treatment of the powder with paraffin, india-rubber, resin, starch, silica, or other inert substances, to diminish the rapidity of combustion and liability to detonation; thirdly, the improved Schultze gunpowder made substantially in the manner set forth.—W. D. B.

*Improvements in Explosive Compounds.* G. G. André, Dorking. Eng. Pat. 13,476, October 11, 1884.

THIS invention relates to the preparation of a compound for use in blasting, of which the combustible and the oxidising agents are kept separate until the explosive is required for use. The combustible consists of a mixture of linseed-oil, paraffin wax, and carbon bisulphide, to which may be added, for the sake of economy, a hydrocarbon liquid. This mixture possesses, at ordinary temperatures, a consistency like that of butter, and does not easily lose its bisulphide of carbon. The oxidising agent consists of powdered saltpetre and potassium chlorate, or the latter alone, contained in a porous envelope of cartridge form. The explosive is prepared for use by immersing for two or three minutes the cartridge containing the oxidising agent in the above described combustible mixture liquefied by heat.—W. D. B.

*Improvements in the Manufacture of Explosive Compounds.* B. Brönes, Vienna. Eng. Pat. 14,140, October 25, 1884.

DOUBLE salts of picrate of sodium with picrate of lead or picrate of barium are prepared by adding one equivalent of picrate of barium or lead to a solution of three equivalents of picrate of sodium, the crystallisation of the double salt being assisted by cooling the solution. These double salts are employed for blasting purposes, preferably in combination with picrate of potassium and nitro-naphthalene, and in addition to these, potassium nitrate, sugar, gum, pure soot and lampblack, may be employed

in conjunction. The proportions of the mixture are chosen according to the purpose to which the compound is to be applied, and can be varied within about the following limits:—

Picrate of barium and sodium .....	30—15%
Picrate of lead and sodium .....	30— 8
Picrate of potassium .....	10— 2
Nitro-naphthalene .....	5—20
Nitrate of potassium .....	20—40
Sugar .....	1½— 3
Gum .....	2— 3
Soot or lampblack .....	½— 4

The nitro-naphthalene employed by preference is a highly nitrated product, consisting of a mixture of the di-, tri-, and tetra-nitro compounds. The inventor claims the employment and application of the double salt compounds of picrate of sodium, with other picrates, and the application, in explosive compounds which contain the above-mentioned double salts, of highly nitrated naphthalene, "for the purpose of obtaining on the one hand the utmost possible oxidation of the carbon; and on the other hand, a slower consumption of the explosive compound through the large quantity of nitrogen contained in the same, and for generally increasing the volume of gas evolved."

—W. D. B.

*Improvements in the Manufacture of Explosive Compounds.* F. Maxwell, Putney, and C. L. J. A. Lewall, Hanover Square. Eng. Pat. 14,379, Oct. 30, 1884.

THIS invention relates to the manufacture of explosive compounds by treating starch with potassium chlorate, and is carried into effect in several ways. First, the starch, previously worked into a thin paste with cold water, is treated with a boiling solution of potassium chlorate, and the gelatinous mass dried, and, if necessary, moulded or granulated. Second, the chlorated starch prepared according to the first method is incorporated with paraffin, vaseline, a hydrocarbon, fatty acid, rosin or gum. Third, the product of either the first or the second process is mixed with charcoal, sulphur, or a metallic sulphide, in order to increase the degree of sensitiveness and rapidity of action. Fourth, bran previously freed from amylaceous matters and gluten by a process of diastatisation is employed in conjunction with the chlorated starch. Fifth, bark, tan, cellulose, or any vegetable fibre is employed in conjunction with the chlorated starch, the latter mixture being added to one of the first-named materials whilst in the semi-gelatinous condition. Sixth, the sensitiveness of the explosive compound prepared according to any of the hereinbefore-mentioned methods is reduced or graduated by a substitution of part of the potassium chlorate by potassium nitrate. As an important advantage attendant upon the conjunction of starch with potassium chlorate, it is claimed that the latter salt shows very little tendency to segregate in crystals when the gelatinous mixture is dried. Hence on drying the mixture of bran with chlorated starch, the crystallisation of the chlorate at the surface of the bran does not occur to anything like the extent which it does in the case of ordinary chlorated bran.—W. D. B.

*Improvements in the Formation or Preparation of Explosive Charges.* E. J. Mills, Glasgow. Eng. Pat. 14,737, November 8, 1884.

THE object of this invention is to obtain a means whereby the rate of combustion of powder contained in a cartridge for propulsive purposes, and in a bore-hole for blasting purposes, may be efficiently graduated. This end is attained by building up the charge of two or more layers of the explosive, the materials of the several layers being such as to burn with different degrees of rapidity.—W. D. B.

*Improvements in Ammunition for Military and Sporting Small Arms and Field Machine and other Guns.* Lieut.-Col. W. Hope, Westminster. Eng. Pat. 14,915, November 12, 1884.

THE object of this invention is to reduce the strain upon the gun set up at the moment of explosion of

the charge, by slightly moving the projectile, or bringing it into equilibrium by a sort of priming charge, and then immediately afterwards igniting the main charge. In the case of large guns, the inventor attained this end by using a cartridge containing a little gun in the centre (Eng. Pat. 2923, July 15, 1880). To adapt this principle to small arms and small guns, the cartridges have an axially arranged cigarette-like core or tube, which may be made of thin paper, charged with powder consolidated by pressure and perforated longitudinally; the primer, detonator, or cap communicates with the said longitudinal perforation. Or the cartridge may be charged with a block or blocks of the powder, consolidated by pressure, and perforated axially from end to end, the primer or detonator communicating with the said axial perforation.—W. D. B.

*Improvements in Propelling Composition and Cartridges for Ordnance.* G. Quick, Gloucester. Eng. Pat. 15,546, November 26, 1884.

THIS invention relates to the manufacture of discs or cakes of meal-powder, gunpowder or other gas-producing composition, and consists in the production of such cakes or discs with a large perforation in the centre, and a number of smaller perforations connected with each other by radial and concentric channels or grooves formed in the surface of the cake by moulding or cutting. The object aimed at is the obtaining rapidity of ignition with uniformity of combustion. In preparing cartridges for ordnance with such discs,

from a distance. In accordance with this, the rocket is provided with a glass or other vessel of oil embedded in a fulminating composition, which is fired by a fuse when the rocket composition proper is spent. Details are given of various mechanical arrangements which the inventor adopts.—W. D. B.

*Improvements in Caps or Apparatus for Exploding Dynamite and other Explosives.* J. Paulus, Berlin. Eng. Pat. 4853, April 20, 1885.

THE object of these improvements is to direct the force of explosion in the direction of the longitudinal axis of the explosive mass in which the detonator is embedded. The general principle is to weaken or otherwise manipulate the bottom of the copper shell, so that the resistance opposed to the force of explosion of the detonating composition is less here than at other points of the shell. The inventor describes a variety of plans in detail, whereby he is enabled to apply this general principle.

—W. D. B.

## XII.—GENERAL ANALYTICAL CHEMISTRY.

*An Electrical Centrifugal Machine for Laboratories.* Alexander Watt. Paper read before Section B, British Association, Aberdeen Meeting.

THE late Dr. Mohr ("Lehrb. d. Chem. Analyt. Titrimethode," 3rd Ed., 1870, p. 684) of Bonn, advocated the use of a centrifugal machine as a means of rapidly dry-

care is taken that the large central orifices in the discs shall be in the centre or axis of the cartridge, and in line with the axial vent of the gun.—W. D. B.

*Improvements in the Manufacture of Gunpowder.* J. N. Heidemann, Cologne. Eng. Pat. 16,314, December 11, 1884.

STRAW is carbonised until it attains a brown chocolate coloured appearance, and the carbonaceous substance obtained is cooled, pulverised, and mixed with potassium nitrate and sulphur, in the proportion of eighteen per cent. of the brown carbonaceous substance, seventy-nine per cent. of potassium nitrate, and three per cent. of sulphur.—W. D. B.

*Improvements in the Construction of Rockets.* J. Whitley, Leeds. Eng. Pat. 3429, March 17, 1885.

THE object of this invention is to provide a means whereby oil may be thrown upon the surface of the sea

ing crystals and crystalline precipitates, but although they are admirably adapted for that purpose, centrifugal machines are seldom seen in our chemical laboratories.

The neglect of this valuable addition to our laboratory apparatus is probably owing to the inconvenience involved in driving the machine at a high speed by means of the ordinary hand-driving gear, especially when the rotation has to be maintained for a considerable length of time. It occurred to me, therefore, that by attaching the drum or basket of the machine (or the rotating table of Mohr's apparatus) directly to the spindle of an electro-motor the difficulty of driving might be got over, and at the same time a combination of great efficiency would result, as the electro-motor, like the centrifugal machine, is most efficient when run at a high speed. The apparatus shown in the sketch consists essentially of a perforated basket A, which is slipped on to a cone attached to the spindle S of an electro-motor, and held in position by the nut B. The casing B, with its removable cover C, serves to receive the liquid driven out of the substance being dried. A flat form of the ordinary Siemens H armature

E, revolves between the poles P, of the electro-magnets M, which are connected by means of the base plate I. The brass cross-bar G carries the top bearing of the spindle S, and prevents the magnet poles from being drawn together.

From four to six cells of a bichromate battery or Faure secondary battery furnish sufficient power to run the machine at a high speed. An apparatus, with a copper basket four inches in diameter, has been found extremely useful in the laboratory for drying such substances as granulated sulphate of copper and sulphate of iron and ammonia, but more especially for drying sugar, which, when crystallised in very small crystals, cannot be readily separated from the syrupy mother-liquor by any of the usual laboratory appliances. For drying substances which act on copper, the basket may be made of platinum or ebonite; in the latter case, owing to the increased size of the perforations, it may be necessary to line the basket with platinum wire gauze or perforated parchment paper.

*Detection and Estimation of Fluorine.* G. Tammann. Zeit. Anal. Chem. 1885, 328.

WÖHLER's method of determining fluorine, by heating with sulphuric acid, in presence of silica, and estimating the loss ( $\text{SiF}_4$ ), is less trustworthy than when the latter is directly estimated by absorption, by  $\text{Ca}^{++}$ . A series of determinations by the latter method (Fresenius, *Ibid.* 5, 190), gave numbers approximating to the theoretical. If sulphurous acid be simultaneously evolved it should be removed by interposing an absorption tube containing chromic acid dissolved in concentrated sulphuric acid. For determining hydrofluoric acid the author recommends precipitation by barium salts ( $\text{BaBr}_2$  as silicofluoride in presence of a soluble silicate, and alcohol (50 per cent.). Accurate results are obtained even with very dilute acids. In cases where barium sulphate is simultaneously precipitated, the precipitate is ignited, the resulting barium fluoride dissolved out by hydrochloric acid, and the residual sulphate estimated. Or the fresh precipitate is digested on the water-bath with a solution of ammonium phosphate, and the resulting barium phosphate dissolved out, after filtering and washing, by means of hydrochloric acid.

In the decomposition of silicon tetrafluoride by water, a process incidental to several methods of analysis, the author calls attention to the formation of an insoluble fluo-silicic compound. After discussing the errors due to this and other defects in some of the usual methods, the author cites the following analysis as conveying the general principles to be observed:—

Potassium silicofluoride was decomposed by sulphuric acid, and the silicon tetrafluoride absorbed in the usual way. The contents of the absorption vessel were rendered alkaline with potash, evaporated to dryness, the residue treated with hydrochloric acid, the excess of the latter subsequently removed by adding potassium acetate. 3 vols. alcohol (80 per cent.) were then added, and after allowing to stand 2–3 hours, the potassium silicofluoride was filtered off, well washed and titrated with potash according to Stolba's method (*Ibid.* 2, 396). The following experimental numbers show the degree of accuracy attainable by this method:—

$\text{K}_2\text{SiF}_6$ taken.	$\text{K}_2\text{SiF}_6$ estimated.	Difference.
0.5582	0.5522	—0.0060
0.2146	0.2128	—0.0018
0.0065	0.0057	—0.0011

The following gravimetric method is recommended in the case of soluble fluorides. Hydrobromic and silicic acids are added to the solution, then barium acetate, and lastly alcohol. The precipitate is washed with alcohol, and then with hydrofluoric acid (on a platinum funnel) to remove silicic acid. The barium silicofluoride may then be weighed as such, or converted into sulphate.

In isolating fluorine from mixture or combination with organic substances, the author finds that it is impossible to avoid considerable loss in the preliminary incineration, even though the substance be previously mixed with barium hydrate or sodium carbonate in relatively large quantity.

For detecting traces of fluorides the author finds the method of Hofstegler (*Handb. Phys. Poth. Anal.* 1875, p. 454) to be one of sufficient delicacy.—C. F. C.

*A New System of Volumetric Analysis.* C. Winkler. Ber. 18, 2527–2533.

IN the introduction to his Text-book of Volumetric Analysis, Mohr points out that it is necessary to make up standard solutions of a certain definite strength, in order to simplify calculations. He suggests that the liter should contain "either one atom, or one-tenth of an atom, in grammes, of the active substance;" and afterwards defines the former as being normal, the latter as deci-normal. Mohr's book was published more than thirty years ago, at a time when dialistic ideas and formulae were still in use, and when atomic and equivalent weights were regarded as identical. Now, however, the old combining weights are no longer in use; the adoption of unitary formulae, the discovery of the law of volumes, and the progress of the theory of valency, have considerably altered our conceptions as to atoms and molecules; so that the old system of volumetric analysis, based upon the theory of equivalents, is not in accordance with our modern atomic and molecular weights.

Taking the weight of an atom of hydrogen as the unit of weight, the corresponding quantities of other substances were naturally represented, on the old theory of equivalents, as follows:—

1 atom of hydrogen = 1	atom of oxygen = 80
1 " " = 1	sodium = 23Na
1 " " = 1	sodium carbonate = 53Na <sub>2</sub> CO <sub>3</sub>
1 " " = 1	hydrochloric acid = 36.5HCl
1 " " = 1	sulphuric acid = 49H <sub>2</sub> SO <sub>4</sub>

The introduction of the idea of molecules, and of atoms of different valency, has apparently destroyed the simplicity of the above relations, for we now regard the following as being corresponding quantities:—

1 atom of hydrogen = 1	atom of oxygen = $\frac{16}{2}$ = 8O
1 " " = 1	sodium = 23Na
1 " " = $\frac{1}{2}$	molecule of sodium carbonate = $\frac{106}{2}$ = 53Na <sub>2</sub> CO <sub>3</sub>
1 " " = 1	hydrochloric acid = 36.5HCl
1 " " = $\frac{1}{2}$	sulphuric acid = $\frac{98}{2}$ = 49H <sub>2</sub> SO <sub>4</sub>

Winkler finds that the necessity for working sometimes with half, and at other times with the whole molecular weight, is a source of great confusion, especially to beginners. The rule frequently given for finding the equivalents (equivalent weight = atomic weight divided by valency) does not remove the difficulty, for according to it we have the relations:—

1 atom of hydrogen = $\frac{1}{3}$	atom of nitrogen = $\frac{14}{3}$ = 4.66 N <sup>III</sup>
1 " " = $\frac{1}{3}$	arsenic = $\frac{75}{3}$ = 25 As <sup>III</sup>

whereas in titrating nitrogen in the form of ammonia with normal acid, or converting  $\text{As}_2\text{O}_5$  into  $\text{As}_2\text{O}_3$  by iodine solution, the equivalent quantities are:—

1 atom of hydrogen = 1	atom of nitrogen = 14 N
1 " " = $\frac{1}{2}$	arsenic = $\frac{75}{2}$ = 37.5 As.

As it is of the greatest importance that the learner should have a clear conception of the theoretical consideration upon which the system of analysis is based, the writer has suggested the adoption of a new unit of weight—namely, the weight of a molecule of hydrogen. Taking this as a standard, the following relations are at once evident:—

The equations upon which the titrations depend are now written in an uniform manner, so that in all cases a molecule of hydrogen ( $\text{H}_2$ ) enters into the reaction; as a

rule this is naturally the case, for in all methods of oxidation and reduction an atom of divalent oxygen comes into play:—

A glance at the equation shows the quantity of a substance which enters into reaction, and also indicates the amount or "normal weight" which must be taken for the standard solution. An experience of 15 years has shown the system to be very convenient and easily understood. One advantage lies in the fact that all normal solutions thus prepared are of equal value. The same oxalic-acid

*Laboratory Apparatus for Operations requiring Exclusion of Air.* N. V. Klobukow. Zeit. Anal. Chem. 1885, 395—399.

THE essential portion of this apparatus (Figs. 1 and 2) consists of the two funnels  $T_1$ ,  $T_2$ , which are bound together at their edges by means of an indiarubber band. In other respects the details of construction require no further explanation. The apparatus may be used for evaporation from the beaker B in an atmosphere of any desired gas, as well as in vacuo or under diminished pressure; for drying a substance contained in the funnel space, in which case B may be used for heating the stream of indifferent gas. So also for washing out a precipitate; and indeed by means of suitable slight

FIG. 1.

FIG. 2.

solution will serve for determining the amount of potash in potash-lye, of ammonia in ammonium sulphate, of carbon dioxide in a cement, or for testing the strength of a permanganate solution.—D. E. J.

*Detection of Chlorides in presence of Bromides and Iodides.* L. L. de Koninck. Zeit. Anal. Chem. 1885, 376—379.

THE method of conversion into chromyl chloride is untrue-worthy, as the chlorides are, under certain circumstances, otherwise decomposed—viz., according to the subjoined equation:—

The following method is therefore recommended: The mixed haloid silver precipitate is digested with 4—5 vols. of a 10 per cent. solution of ammonium sesquicarbonate, for some minutes in the cold. On filtering and adding a drop of a solution of potassium bromide, the presence of a chloride is revealed by a precipitate of silver bromide.—C. F. C.

variations in the arrangement, for any operation requiring the condition in question.—C. F. C.

*New Reaction of Titanic Acid.* R. Fresenius. Zeit. Anal. Chem. 1885, 410—412.

SOLUTION of titanic acid in hydrochloric or sulphuric acid give with hyposulphurous acid—such as is obtained by the action of zinc upon sulphurous acid—a red coloration, soon passing into yellow. The coloration is striking, with solutions containing 1·5 titanic acid per 1000. With smaller quantities the column of liquid under observation must be correspondingly increased. Inversely, of course, titanic acid may be used to detect the presence of hyposulphurous acid.—C. F. C.

*Composition of Commercial Sulphate of Quinine.* W. Koppeschaar. Zeit. Anal. Chem. 1885, 362—376.

THE stated object of this paper is the strong recommendation by the author of the optical method of examination of commercial alkaloids. The advantages of the method are brought out by the experimental results detailed.

Incidentally the author discusses the cause of the variation in the statements as to the molecular proportion of the water of crystallisation of salts of the alkaloids. He points out that mixtures of alkaloids are in regard to certain properties compound molecules, the properties of which are not the mean of those of the constituents. Quinine sulphates he regards as crystallising with 8 mols.  $H_2O$ .—C. F. C.

*An Apparatus for Rapid Reduction of Gas-volumes to the Normal Pressure and Temperature.* C. Winkler. Ber. 18, 2533–2535.

Two tubes A and B are connected together below by strong indiarubber tubing; B is simply a levelling tube, while A serves as the measuring tube, and is provided with a bulb and tightly-fitting stop-cock above. The tubular portion of A is carefully graduated in cubic centimetres, so that volumes from 95cc. to 125cc. (reckoned from the stop-cock downwards) can be read off to within one-tenth. These limits correspond to the volumes which 100cc. of air, measured at normal pressure and temperature, and saturated with aqueous vapour, would occupy at 800mm. and 0° C., and 700mm. and 30° C. respectively, so that the graduation is sufficiently extensive for all ordi-

lowering the levelling tube B, the level of the mercury in A is altered until the calculated volume is enclosed; the stop-cock is then shut. Now the volume of the enclosed air will increase or diminish with the variations of atmospheric pressure and temperature, in the same ratio as the volume of any quantity of gas whose normal volume we wish to determine; so that if the latter be placed in the same room as the apparatus, and if B be raised or lowered until the mercury stands at the same height in both tubes (the stop-cock being always closed), the normal volume of the gas under investigation can easily be found by a simple proportion.

The apparatus is made by Franz Huguershoff, Leipsic.

—D. E. J.

*A Combined Exhaustion and Compression Apparatus.* A. Gawalowski. Chem. Centr. Blatt. 16, 465–467.

THE apparatus is shown complete in Figs. 2 and 8, and in Figs. 1 and 7 in section (p. 758). The two balloons are of glass and are connected by a metal fastening; the tubes A and E are for the entrance and egress of the air as shown by the arrows, and in the larger form (Fig. 2) serve also as an axle by which the apparatus may easily be reversed. Figs. 3 and 6 show different methods for opening and shutting the two tubes; those parts which

nary conditions. The apparatus is regulated once for all, by introducing into the measuring tube 100cc. of moist air, measured at N.P.T. This is best done as follows: A convenient quantity of mercury is poured into the tubes, a few drops of water are allowed to trickle down into A, and then the barometric pressure and the temperature are very carefully determined. By means of the formula—

$$V = \frac{(760 - 4 \cdot 5) \times 100 \times (273 \times t)}{273 \times (18 - t)}$$

the volume is calculated which 100cc. of moist air, measured at N.P.T., would occupy under the same circumstances. The stop-cock is opened, and by raising or

are made of caoutchouc having the dotted shading. The automatic action of this apparatus, at once an exhaust or pressure pump, is brought about by an arrangement of automatic valves in the suction-tube B, and in the exit-pipe for the water D. For valves the arrangements Figs. 1, 3, 4, 5 and 6 are recommended for choice. Fig. 4 represents a valve consisting of a massive metal bell, or one covered with indiarubber, which sits in a caoutchouc ring and perfectly fits it. The narrowed part of the tube above the ball has a waved outline (see section Fig. 4a) so that air communication is established at m, n and o. However, by affixing the air-communication tubes (Fig. 5) this object is also attained.

FIG. 7.

FIG. 8.

The construction shown in Figs. 6 and 7 is based on the use of clapper-valves lined with caoutchouc (see Fig. 7). The apparatus can also be made to serve as a gas-holder.

The small apparatus (Fig. 8) can be recommended for exhaustion or pressure in the case of chemical analyses, whilst the larger one (Fig. 2) does good service for increasing the pressure of illuminating gas, and as an air pump, the use of water service-pipes not being needed.—S. R.

#### *Analysis of Platinum Ores.* Th. Wilm. Ber. 18, 2536-2551.

THE author discusses in a long and interesting paper the various methods proposed for the quantitative estimation of platinum, its separation from the other platinum metals and the separation of the whole of these metals from the base metals Fe, Cu, and Ni, occurring in the ores. The method proposed by Claus—viz., the reduction of the higher chlorides to subchlorides by boiling with NaOH solution and precipitation with  $\text{NH}_4\text{Cl}$ , whereby platinum double chloride alone is precipitated—is not here applicable, as the action of caustic soda has only been studied to a limited extent. According to Rose, the action of  $\text{Na}_2\text{CO}_3$ ,  $\text{Na}_2\text{HPO}_4$ , and  $\text{BaCO}_3$  would precipitate rhodium completely, together with a little palladium. The action of mass as illustrated by a mixture of the metals gives totally different results.

1	2	3	4	5	6	7	8
Precipitated with $\text{NH}_4\text{Cl}$	After treatment with $\text{Na}_2\text{CO}_3$	After treatment with $\text{Na}_2\text{HPO}_4$	After treatment with $\text{BaCO}_3$	Precipitated with $\text{H}_2\text{S}$	After fusion with $\text{Na}_2\text{CO}_3$	After treatment with NaOH and $\text{NH}_4\text{Cl}$	After treatment with $\text{BaCO}_3$ in hot solution.
78.91	77.12	77.24	77.62	76.82	76.71	71.78	54.61
78.51	77.57	—	77.11	—	76.8t	—	—
—	—	—	77.08	—	76.42	—	—

The experiments and results may be briefly stated as follows:—In the first place the ore was dissolved in aqua regia, and the solution filtered from osmiridium and gangue. One portion of the solution was precipitated with  $\text{NH}_4\text{Cl}$ , and the double chlorides weighed, a second was previously treated with  $\text{Na}_2\text{CO}_3$ , a third with  $\text{Na}_2\text{HPO}_4$ , a fourth with  $\text{BaCO}_3$ , and the platinum metals determined in the filtrate. A fifth portion was precipitated with  $\text{H}_2\text{S}$ , and the sulphides digested with nitric acid to dissolve out the Cu. In a sixth portion of the solution, the filtrate from the carbonate or phosphate of soda was evaporated to dryness and fused with carbonate of soda in order to reduce the platinum compounds to the metallic state. The seventh process consisted in heating the chlorides with NaOH solution, whereby a portion of the salts is reduced to subchlorides and not precipitated with  $\text{NH}_4\text{Cl}$ . Experiment No. 8 proves (Rose's statement being incorrect) that  $\text{BaCO}_3$  precipitates in a hot solution considerable quantities of the platinum metals. The results are given in the above table.

In every case a complete separation of iron and copper was found impossible. Another method with an equally unsuccessful result consisted in precipitating the solution of the ore with iron and extracting the precipitate with aqua regia. In spite of their solubilities, palladium, platinum, gold, and also iron, copper, and traces of nickel remain undissolved.

It is a remarkable fact that by the action of  $\text{H}_2\text{S}$  on an acid solution of the ore, iron is invariably precipitated, and neither this metal nor copper can be extracted with nitric acid.

On digesting the sulphides with yellow ammonium sulphide, PdS dissolves most readily, and at the same time CuS to an extent never observed in the presence of any other metal than Pd.

The author has also tried the method of electrolysis, and finds that with the Pt metals, Cu and Fe are deposited both in HCl and  $\text{HNO}_3$  solution. These results appear to point to the conclusion that Fe and Cu are not present in the ores as mixtures; but form a much closer combination. Interesting facts respecting the separation of the Pt metals from one another are given, but do not admit of useful abstraction.—J. B. C.

## New Books.

THE DYEING OF TEXTILE FABRICS. By J. J. HUMMEL, F.C.S., Professor and Director of the Dyeing Department of the Yorkshire College, Leeds. Cassell & Co. Limited: London, Paris, New York, and Melbourne. 1885.

OCTAVO volume bound in cloth, price 5s.; containing Preface by the author, Table of Contents, List of Illustrations (97 in all) and 527 pages of subject matter. An Alphabetical Index concludes the work. The first 43 pages of the work contain matter treating in a very clear, as well as concise manner, of the

various textile fibres:—I. Cotton. II. Flax, Jute and China Grass. III. Wool. IV. Silk.

Next follows a chapter on THE OPERATIONS PRELIMINARY TO DYEING—viz., V. Cotton Bleaching. VI. Linen Bleaching. VII. Wool Scouring and Bleaching. VIII. Silk Scouring and Bleaching. The important subject of WATER IN ITS APPLICATION TO DYEING, then comes under consideration, with certain of the various methods proposed for purifying it. THE THEORIES OF DYEING are treated of in Chapter X., and the USE OF MORDANTS in Chapter XI., introducing the reader to the METHODS AND MACHINERY USED IN DYEING described in Chapter XII.

Chapters XIII. to XV. are devoted to the APPLICATION OF THE NATURAL COLOURING MATTERS, and those furnishing blue, red and yellow tints are specially considered. Chapters XVI. to XXI. deal with the APPLICATION OF THE ARTIFICIAL COLOURING MATTERS; Chapter XXII., treating of the APPLICATION OF THE MINERAL COLOURING MATTERS. THE DYEING OF MIXED FABRICS (Cotton and Wool) is the subject of Chapter XXIII. An exceedingly interesting and useful Chapter for the teacher of Practical Dyeing, as well as for the student, is Chapter XXIV., on the METHOD OF DEVISING EXPERIMENTS IN DYEING. Chapter XXV., ESTIMATION OF THE VALUE OF COLOURING MATTERS, and Chapter XXVI., THE DETECTION OF COLOURS ON DYED FABRICS, with the valuable Tables of Colour Tests, will be of great service.

The truly scientific spirit in which the whole work is written very greatly commends this excellent little work to students of Applied Chemistry, as well as to chemists in dye- and print-works laboratories.

#### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

- 14033 J. Lee, Halifax. Improvements in the construction of the flues of steam boilers for the consumption of smoke. November 17  
 14045 W. R. Lake, London.—Communicated by J. H. Blessing, United States. An improved method of and apparatus for preventing incrustation in steam boilers. Complete specification. November 17  
 14112 F. Siemens, London. A method of lining furnaces. November 18  
 14648 J. Powell and L. Roberts, London. Improvements in open hearth regenerative furnaces. November 28  
 14708 J. Temple, London. Improvements in surface condensers. November 20  
 14883 J. K. Broadbent, Salford. An apparatus for introducing calcined steam, and improving the combustion of steam boiler furnaces. December 1  
 15129 P. E. C. Stromeyer, London. Distilling fluids—viz., "An improved distilling apparatus." December 9  
 15146 J. Kirkaldy, London. Improvements in condensers and distillers. December 9  
 15252 P. M. Jusee, London.—Communicated by C. Dietzsch, Germany. Improved process of and furnaces for burning limestone or lime and similar materials. Complete specification. December 11  
 15439 E. Fontenilles, Paris. Apparatus for evaporating and concentrating liquids generally. December 16  
 15482 J. Settle, Manchester. Improvements in furnaces. December 17

#### II.—FUEL, GAS, AND LIGHT.

- 14218 T. Charlton and C. S. Wright, Barnsley, and J. Wright, London. Improvements in the method of carburetted or charging atmospheric air, or gases or vapours, or combinations of these, with petroleum, naphtha, or other such hydrocarbon liquids, preparatory to using them either for producing motive power by explosion, or the generation of heat, or as illuminants by slower burning. November 20  
 14269 P. Tarbutt, London. Method of effecting combustion of liquid fuel. November 21  
 14283 E. Edwards, London.—Communicated by C. F. Sebillé and A. Colard, France. Improvements in artificial fuel. November 21  
 14336 B. Redwood, London. Improvements in measuring and delineating the flame of a lamp. November 23  
 14392 F. S. Dobson and A. Murfet, London. Improvements in heating and supplying air to assist combustion and consume smoke in steam boiler and other furnaces having firebars, and in apparatus therefor. November 24  
 14549 J. K. Jones, London. Improvements in ovens for making breeze and coke. November 27  
 14720 H. Simon, London. An improvement in the manufacture of coke. December 1  
 14771 S. Kocherthaler, London. Improvements in apparatus for regulating the supply of heat for heating rooms, and for similar purposes. December 1  
 14859 J. S. Salfery, London. Improvements in the manufacture of artificial fuel. December 3  
 14865 J. Neil, Glasgow. Improvements in or connected with the burning of hydrocarbon or mineral oils, and other such liquid fuel in steam boiler and other furnaces, and in apparatus therefor. December 3  
 15104 D. R. Gardner, Glasgow. Increasing the illuminating power of gas. Complete specification. December 9  
 15181 Leo Kumberg, London. A pneumatic hydrocarbon illuminating apparatus. Complete specification. Dec. 10  
 15201 W. Clark, Glasgow. Improvements in gas lamps. December 11  
 15286 C. A. von Welsbach, London. Manufacture of an illuminant appliance for gas and other burners. December 12  
 15291 J. B. Butterfield, Halifax. An improved treatment of furnace gases for drying and heating purposes. December 12  
 15331 A. Kinner and E. Fahrigr, London. An improved apparatus for carburetted and increasing the illuminating power of gas. December 14  
 15419 A. Gutenson, London. Improvements in obtaining gas from hydrocarbons. December 16  
 15470 C. Blagburn, London. Improvements in apparatus for burning liquid fuel in furnaces, specially applicable to the furnaces of marine boilers. December 16

#### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

- 14991 J. C. Hamilton, Glasgow. Improved apparatus for the distillation of shale and other nitrogenous and bituminous substances. December 5

#### IV.—COLOURING MATTERS AND DYES.

- 14222 E. Elsaesser, London. Improvements in the manufacture of azo-dyes, or colouring matters. Complete specification. November 20  
 14241 J. Y. Johnson, London.—Communicated by the Farbenfabriken vormals F. Bayer & Co., Germany. Improvements in the manufacture of azo dyes. November 21  
 14802 A. E. Hudson, J. Bartley, and F. Best, Improvements in laundry blue. Complete specification. December 2  
 14862 H. H. Lake, London.—Communicated by A. Leonhardt & Co., Germany. Improvements in the manufacture of colouring matters. December 5  
 15296 P. Jenson, London.—Communicated by the Actien-Gesellschaft für Anilin-fabrikation, Germany. Process for the production of mixed azo colours. December 12  
 15357 H. Hasencamp and The Farbenfabriken vorm. Bayer & Co., London. Improvements in the manufacture of colouring matters for dyeing and printing. December 11  
 15381 J. Y. Johnson, London.—Communicated by F. von Heyden Nachfolger, Germany. Improvements in the production of azo dyes. Dec. 15

#### V.—TEXTILES: COTTON, WOOL, SILK, ETC.

- 15391 M. E. Oohn, London. A process for treating vegetable spinning fibres. Complete specification. December 15

#### VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

- 14034 R. H. Ainsworth and E. B. Manly, London. Improve- ments in the construction of apparatus for scouring, washing dyeing, and other analogous purposes. November 17  
 14637 J. C. Mewburn, London.—Communicated by La Société Leblois, Nicot, et Cie, France. Improvements in bleaching cotton, and in apparatus therefor. November 27  
 15438 W. Watson, jun., Glasgow. An improved method of obtaining baths of chloride of antimony for use in dyeing and calico printing. December 16

#### VII.—ACIDS, ALKALIS, AND SALTS.

- 14027 A. P. Laurie, London. Improvements in the manufacture of soda. November 17  
 14120 W. Thomlinson and D. Crawford, London. A new or improved process for the separation of phosphorus from "basic process" slags, or other materials containing phosphorus, and for the subsequent treatment thereof to convert the phosphorus into phosphates. November 18  
 14123 D. Maher, Liverpool. Improvements in lids applicable for caustic drums and other like articles. November 18  
 14279 G. H. Bolton and J. Leathwood, Liverpool. Improvements in lids applicable to caustic soda drum heads and to other purposes. November 21  
 14361 E. W. Parnell and J. Simpson, Liverpool. Improvements in the manufacture or production of sulphur and sulphuric acid. November 24  
 14365 J. Simpson and E. W. Parnell, Liverpool. Improvements in the manufacture of bicarbonate of soda. November 24  
 14526 M. Wolff, Liverpool. Improvements in or appertaining to the manufacture of table salt. November 26  
 14531 J. Lea, London. Improved method of operating upon zinc ore, and the production of chloride of lime from such treatment. November 26  
 14629 C. Wigg, Liverpool. Improvements in the treatment of alkaline liquors. November 28  
 14780 L. E. L. J. R. Reid and L. M. C. Folie-Desjardins, Paris. Process and apparatus for the manufacture of sulphuret of carbon. Complete specification. December 2

#### VIII.—GLASS, POTTERY, AND EARTHENWARE.

- 14127 M. F. C. A. Oppermann, London. An improved mode of producing window glass, and apparatus to be used there with. November 18  
 14159 G. Johnson and J. Lockwood, Glasgow. Improvements in the construction of china or other tiles for fastening purposes. November 19  
 14164 J. Howie, Glasgow. Improvements in the manufacture of glazed or enameled clay goods or ware. November 19  
 14225 B. J. B. Mills, London.—Communicated by P. A. Mignot, France. Improvements in the manufacture of ceramic pastes or bodies, to be used principally in the production of faience articles in porcelain. November 20  
 14273 J. Rogers, London. Improvements in the apparatus for drying China clay or similar substances. November 21  
 14462 J. M. Benzell, London. Improvements in the manufacture of articles of glass, porcelain, earthenware, and the like. November 21  
 14468 T. Bolas, Chiswick. Decorating or imprinting devices upon glass, metal, stone, pottery, enamel, asbestos slabs or sheets, or other materials which will withstand the action of fire. November 25  
 14523 D. Rylands, Stairfoot, Yorkshire. Improvements in means for moulding or pressing glass. November 27

- 14628 W. H. Hales, Birmingham. Improvements in machinery for moulding pottery-ware. Complete specification. November 28.
- 14947 A. E. Muller, London. Process for the production of rubbing or igniting surfaces on porcelain and other earthenware and stoneware. December 5.
- 15118 H. Hill, Nottingham. An improvement in the manufacture of earthenware used for domestic purposes. December 10.
- 15329 A. J. Boulton, London.—Communicated by A. Schierholz, Germany. Improvements in the manufacture of ceramic ware. December 14.
- 15447 A. Wilkins, London. Improved method of operating on glass for producing ornamental effects on or in the surface thereof. December 16.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

- 14664 H. Mather, London. Improvements in manufacture of cement and lime. Complete specification. November 17.
- 14665 E. Robbins, London. A new or improved tesserae or mosaic material for building and other purposes. November 17.
- 14533 W. Brierley, Halifax.—Communicated by F. G. Kohlmann, Germany. Improvements in the manufacture of bricks and tiles. November 27.
- 14539 R. B. Lee and J. Hodgson, Manchester. Improvements in the construction of fire-proof pillars and columns. November 27.
- 14710 L. A. Groth, London.—Communicated by A. Mark, Germany. A new or improved method of making gypsum boards for preparing rooms instantly in a dry condition. December 1.
- 14725 R. B. Lee and J. Hodgson, Manchester. Improvements in the manufacture of concrete slabs, blocks, pipes, and other articles and parts. December 1.
- 14726 R. B. Lee and J. Hodgson, Manchester. Improvements in the manufacture of concrete fire-proof building materials and parts of buildings, safes, strong-rooms, and other analogous fire-proof structures and receptacles. December 1.
- 14845 L. White, London. Improvements in the manufacture of Portland cement. December 2.
- 14884 A. E. Carey and A. J. Jack, Liverpool. Improvements in the manufacture of Portland cement. December 4.
- 15361 E. G. Colton, London.—Communicated by F. Frenzel, United States. Improvements in the manufacture of encaustic tiles. December 15.
- 14528 G. Chapman, Glasgow. Manufacturing a cement suitable for lining steel and other furnaces, or for being made into bricks with which steel and other furnaces could be lined. December 16.
- 15319 H. Bonnycastle and T. M. R. Jones, Lee. An improvement in the manufacture of refractory and non-conducting bricks, blocks, tiles, slabs, and pipes. December 17.

## X.—METALLURGY, MINING, ETC.

- 14633 H. E. Newton, London.—Communicated by A. Nobeli, France. An improved mode of disintegrating rock by heat. November 17.
- 14608 D. Edwards and R. Lewes, London. Improvements in coating metal plates with tin or other metal. November 17.
- 14736 J. Lewdwaite, London. An improved method of producing malleable castings. November 18.
- 14112 F. Siemens, London. A method of lining furnaces. November 18.
- 14113 F. Siemens, London. Regenerative gas furnace for continuous reduction of iron ores. November 23.
- 14638 W. F. Richards, London. Improvements in the production of aluminium. November 19.
- 14124 E. Morewood, London. Improvements in coating sheets, plates, and other pieces of metal. November 20.
- 14726 W. E. Everett, London. Improvements in casting hollow metallic ingots for the manufacture of metallic tubes, and in moulds for casting the said hollow ingots. November 21.
- 14325 R. Gratzel, London. Improvements in the production of aluminium and aluminium-bronze. November 23.
- 14308 C. Hargrove, Olton. A new and improved method of producing aluminium and its alloys. November 24.
- 14111 R. Heathfield, London. An improvement or improvements in utilising waste products obtained in galvanising iron. November 24.
- 14636 L. J. D. Monchel, London. The manufacture of magnesium bronze. November 28.
- 14736 W. Scott, Wandsworth. Improvements in blast-furnaces. December 1.
- 14924 W. P. Thompson, Liverpool.—Communicated by C. Hessefrel, Russia. Improvements in producing malleable iron or steel direct from the ore, and apparatus therefor. Complete specification. December 5.
- 15062 M. H. Hurrell and E. Easton, London. Improvements in the apparatus to be used in the treatment of ores and refuse metals. December 8.
- 15170 J. D. Grey, London. Improvements in the method of rolling steel and iron bars or plates for the manufacture of tin andterne plates. December 10.
- 15259 M. H. Hurrell and E. Easton, London. Improvements in the treatment of ores, and in apparatus to be used thereof. December 11.

- 15294 A. J. Boulton, London.—Communicated by T. S. Sohne, Germany. Improvements in the coating of hardware. December 12.
- 15357 S. Thomas, Newport, Mon. Improvement in coating tin plates. December 15.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

- 14380 R. Ross, Pudsey. Improvements in the manufacture of soap for toilet and cleansing purposes. November 24.
- 14669 E. Mansfield and A. P. Rivolta, London. Process and apparatus for removing oil, fat, and other foreign matter from tallow, waste, wool, silk, rags, oil-cloth, and other fibrous material. November 30.
- 14957 C. D. Abel, London.—Communicated by the Fabrik Chemischer Produkte Actien Gesellschaft, Germany. Improvements in the separation and treatment of fatty matter from compounds containing wool fat. December 5.

## XII.—PAINTS, VARNISHES, AND RESINS.

- 14128 J. B. Spence, London. Improvements in the preparation of materials to be used in making paint. November 18.
- 14663 E. J. Digby, London. Making black lead. November 30.
- 15131 A. McLean and R. Smith, London. Improvements in the preparation of coloured varnishes. December 9.
- 15135 A. McLean and R. Smith, London. Improvements in the manufacture of pigments. December 9.
- 15231 J. Blackinsep, London. An insulating medium for protecting iron and steel ships' plates and other submerged surfaces of iron and steel from the corrosive or electro-galvanic action set up between the iron or steel plates and materials used in anti-fouling compositions. December 11.
- 15144 R. Wright and C. Wright, London. The royal patent liquid stove polish. December 16.
- 14717 C. D. Abel, London.—Communicated by E. Schaaf, Germany. An improved manufacture of turpentine from the resins of conifers. Complete specification. December 16.

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

- 14533 S. F. Upington and W. J. Goulborne, London. Improvements in leather compositions made with waste leather for various useful purposes and objects. November 23.
- 14111 E. Edwards, London.—Communicated by C. Rollen-Cornelle, France. Improvements in the process of and apparatus for tanning leather. November 24.
- 15226 J. Turcell, London. Improvements in grounding machines or apparatus for fleshing, paring, and stoning chamois, kid, and other leathers. December 17.

## XIV.—AGRICULTURE, MANURES, ETC.

- 14131 J. B. Spence, London. Improvements in the manufacture of fish manure. November 25.
- 14159 H. Hencke, J. Palm, and E. Seelig, London. Improvements in the method of and apparatus for making fodder from certain waste products. November 25.

## XV.—SUGAR, STARCHES, GUMS, ETC.

- 14067 J. Richmond and W. Whiting, London. Improvements in and connected with machinery for sawing and cubing loaf sugar. November 17.
- 14175 J. G. Chapman, London. Improvements in and relating to sugar cane mills. November 24.
- 15750 L. Sternberg, London. An improved process for extracting sugar from saccharine fluids. Complete specification. December 17.

## XVI.—BREWING, WINES, SPIRITS, ETC.

- 14125 J. Hodson, London. Improvements in and apparatus for tinning or cleansing beer. November 24.
- 14887 T. P. Chittenden, London. An improved method of aerating and attenuating worts and other liquors, and securing a pure germless atmosphere wherein to carry on fermentation. December 3.
- 15063 A. W. Gillman and S. Spencer, London. Improvements in the manufacture of finings for sour beer, brewers' wash, and returns. December 3.
- 15168 F. Keeling, London. Improvements in preparation of finings for clarification of beers and wines. December 10.

## XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

### (A) CHEMISTRY OF FOODS.

- 14233 J. E. Taylor.—Communicated by W. Peacock, Australia. Improvements in the preservation of fruit. November 20.
- 14552 B. H. Twaite, Liverpool. Improvements in method of preserving animal and vegetable food and liquids. November 27.

- 11661 J. Sharnman, Sheffield. A new and improved means and method of cleansing and preserving English and foreign fruits. November 30  
 11667 H. Fischon, London. Improved treatment of alimentary substances for their preservation, and apparatus for that purpose. November 30  
 13387 J. Hooker, London. Improvements in the preservation of condensed milk, and of milk either condensed or in the natural state, in admixture with other alimentary matters and medicinal matters or mixtures, or preparations of such matters. December 13

## (B) SANITARY CHEMISTRY.

- 11322 J. B. Scammell, London. Improvements in the methods of filtering water for drinking and other purposes. November 23  
 1372 A. Bell, Manchester. Improvements in apparatus for use in softening or purifying water. November 21  
 11330 F. R. Lipscombe, London. An apparatus for the softening and purifying of water. November 21  
 11855 W. F. B. Massey-Mannering and J. Edmunds, London. Improvements in arrangements for use in oxygenating water contaminated with organic matter. December 2  
 15102 J. A. Drake and R. Muirhead, London. Improved means and appliances connected with the separation of liquids from sewage and like matters, in what are termed filter presses. December 13

## (C) DISINFECTANTS.

- 11291 H. Endemann, London. Improvements in disinfectant and cleaning liquid. Complete specification. November 21  
 15002 W. J. Bishop, London. Automatic apparatus for mixing liquid disinfectants with water, with or without spray. December 9

## XXVII.—ELECTRO-CHEMISTRY.

- 11037 A. Burjorji, London. Improvements in thermo electric batteries. November 17  
 11288 J. A. Berly, London—Communicated by Z. T. Granmle, France. Improvements in dynamo-electric machines. Complete specification. November 21  
 11297 C. Reiss and F. Hecht, London. Improvements in galvanic batteries. November 21  
 11355 T. V. Hughes and C. R. Chambers, London. Improvements in the manufacture of carbons for electric lighting. November 23  
 11381 J. T. Armstrong, London. Improvements in the construction of electrical batteries. November 21  
 11382 J. T. Armstrong, London. Improvements in or relating to materials used in electrical batteries as substitutes for the ordinary exciting liquids. November 21  
 11383 J. T. Armstrong, London. Improvements in certain elements for electrical batteries. November 21  
 11381 J. T. Armstrong, London. Improvements in porous plates for electrical batteries. November 21  
 11388 M. Immisch, London. Improvements in dynamo-machines. November 21  
 11413 H. Aron, Glasgow. Improvements in electric batteries. November 25  
 11565 E. C. C. Stanford and T. J. Jones, London. Improved compounds for electrical and other purposes. December 1  
 11958 O. Marsh, F. E. Burke, and W. Webster. Improvements in electric batteries. December 5  
 11986 G. J. Atkins, London. A new or improved electric and storage battery. December 7  
 13105 J. A. Kendall, Liverpool. Improvements in cells for generating electricity. December 9  
 13285 B. Pell, London. An improvement in manganese voltaic batteries. December 12  
 13455 J. C. Mewburn, London—Communicated by W. Main, United States. Improvements in electro-motors and dynamo-electric machines. Complete specification. December 16  
 13535 R. P. Selson and J. S. Selson, London. Improvements in dynamo-electric machines. December 17

## XIX.—PAPER, PASTEBOARD, Etc.

- 11670 F. M. Hill, New York. A chemical safety paper for cheques, bills of exchange, draughts, and legal documents. November 30

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

- 11001 A. G. Brookes—Communicated by T. S. Nowell, United States. Improvements in the manufacture of lactates. November 17  
 11002 A. G. Brookes—Communicated by T. S. Nowell. Improvements in acid bases for acetated and other beverages and tonics. November 17  
 11003 A. G. Brookes—Communicated by T. S. Nowell. Improvements in laxative compounds. November 17

- 11645 J. H. Bringes and P. T. Goodwin, London. Improved apparatus for boiling fruit or vegetables, or for distilling or obtaining extracts of flowers, oils, or other substances in a vacuum. November 25

## XXI.—EXPLOSIVES, MATCHES, Etc.

- 11051 H. F. Clark, London. Improvements in torpedo railway signals. November 17  
 11652 O. Hoven, London. Improvements in the manufacture of gunpowder. November 17  
 11145 H. R. Smith, London. Improvements in the manufacture of brown "charcoal" for gunpowder. November 18  
 11112 C. H. Abel, London—Communicated by F. Gaens, Germany. An improved explosive compound for guns or firearms and blasting purposes. November 21  
 11887 W. Beaton and J. Moore, Rotherham. An improved method of using explosive or fog signals on railways. December 1  
 11916 C. Wells, London. An improvement in matches. December 4  
 15089 A. M. Clark, London—Communicated by E. Turpin, France. A new explosive, processes of preparing and using the same, and shell charged therewith. Complete specification. December 8  
 15129 E. Schultz, London. Improvements in the manufacture of gunpowder and similar explosives. December 9  
 15528 C. E. Bichel, London. Improvements in explosive compounds. Complete specification. December 17

## ENGLISH PATENTS PUBLISHED.\*

APPLIED FOR DURING 1884 AND 1885.

## I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

1881.

- 16882 H. Hassal. Fire-places or furnaces for heating pottery, brick, and other kilns or ovens. 6d

1885.

- 973 G. S. Hazlehurst. Apparatus for evaporating and concentrating liquids, and depositing their contents. 8d  
 11837 W. Davidson. Kilns for drying granular substances. 8d  
 3212 J. H. Johnson—Communicated by F. and R. Quarcz. Filter presses. 6d  
 12195 W. J. Thompson—Communicated by A. Backus, jun. Improvements in furnaces. 8d

## II.—FUEL, GAS, AND LIGHT.

1881.

- 13338 J. Burgess. Manufacture of candles. 6d  
 17108 W. G. Little. Apparatus for carburetting gas for lighting purposes. 6d

1885.

- 690 J. F. Schnell and J. Read. Obtaining gas for illuminating and other purposes. 6d  
 13370 J. Jefferies. Apparatus for charging gas retorts. 8d  
 16231 L. Chandor. A tischolin candle. 8d

## IV.—COLOURING MATTERS AND DYES.

1885.

- 1108 T. Copley. Production of tanning and dyeing materials. 1d  
 3803 H. J. Haddon—Communicated by F. Bayer & Co. Colouring matters obtainable by the combination of tetrazoditryl or tetrazodixyl-salts with alpha- and beta-naphthylamine or their mono- and disulpho-acids. 1d

\*Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr H. Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.	.....	2d.
Above 8d. and not exceeding 1s. 6d.	.....	3d.
" 1s. 6d. " " 2s. 6d.	.....	14d.
" 2s. 6d. " " 3s. 6d.	.....	2d.

## V.—TEXTILES: COTTON, WOOL, SILK, ETC.

1884.

17083 J. Smith and P. W. Nicolle. Treating vegetable fibres for the extraction of extraneous matters therefrom. 4d

1885.

6509 H. H. Lake.—Communicated by A. Sandron. Water-proofing and preservation of linen and other fabrics composed of vegetable substances. 4d

14694 F. E. Redfern.—Communicated by E. Frémy and V. Urban. Obtaining and treating fibres from plants of the Urtica family, etc. 4d

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

1885.

6471 A. M. Clark.—Communicated by — Berrubé. Dyeing cotton in hanks. 10d

## VII.—ACIDS, ALKALIS, AND SALTS.

1881.

16636 E. C. and F. M. Allan. Manufacture of acetic acid, and apparatus therefor. 6d

16959 H. L. Pattinson, jun. Manufacture of hydrates of barium and strontium. 4d

1885.

151 L. Q. Brin and A. Brin. Manufacture of anhydrous oxide of barium. 4d

1567 T. D. Owen. Treatment of vat liquor for elimination of impurities, and recovery and reuse of re-agents employed. 4d

197 J. Robinson. Treating spent oxides of iron, etc., to obtain sulphur and arsenical compounds. 6d

731 T. Twynam. Production of chlorine and hydrochloric acid from solutions of chloride of calcium. 4d

757 E. F. Trachsel. Process of purifying hydrate of strontium. 4d

156 L. A. Groth.—Communicated by R. Gratzel. Manufacturing the halogen salts of aluminium and beryl. 4d

1800 F. K. Musgratt and G. Eschellmann. Manufacture of magnesium chloride. 4d

3945 A. French. Obtaining ammonium chloride and cyanogen compounds. 4d

6441 H. Trecht. Obtaining carbonate of potash by the Leblanc process. 6d

7857 E. W. Parnell and J. Simpson. Separation of sulphuretted hydrogen from nitrogen. 6d

8888 W. P. Thompson.—Communicated by J. and F. Weeren. Obtaining silicates of the alkalis and alkaline earths from the corresponding sulphates, with sulphurous acid or sulphur; and apparatus therefor. 8d

12341 J. Webster. Utilisation of waste liquors containing calcium chloride. 4d

## REPRINT.

2903 of 1877 J. Mason. Treatment of residues from the production of sulphuric acid. 4d

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

1885.

4186 E. Ormerod. Apparatus for and mode of production of paving slabs, blocks, sinks, tiles, etc., in concrete, in terracotta, etc. 8d

8736 H. W. Merritt. Plastic compounds. 6d

## X.—METALLURGY, MINING, ETC.

1884.

15641 A. G. Brookes.—Communicated by H. J. F. Niewerth. Metallic alloys or compounds. 4d

13812 J. D. Grey. Manufacture of sheet iron and steel. 4d

16135 H. Munkitell. Extracting gold by means of chlorine from ores, sand, residues, etc. 8d

17039 R. Buchanan. Drying chambers for founders' moulds and cores. 6d

1885.

230 J. M. H. Munro and T. Wrightson. Treatment of "basic cinder." 6d

870 J. H. Johnson.—Communicated by the Société Anonyme "Le Ferro Nickel." Manufacture of metallic alloys. 4d

1031 E. von Puttner. Extraction of magnesium. 4d

1573 G. Lowe and H. Levetus. Improved alloy for mercurial gilding. 4d

7009 T. May. Gas-producing furnaces for smelting metals, etc. 8d

10695 C. Cochran. Improvement in working blast furnaces. 4d

## REPRINT.

1115 of 1838 Treatment of iron ores, etc. 6d

## XII.—PAINTS, VARNISHES, AND RESINS.

1885.

12508 W. R. Lake.—Communicated by L. Brown. Manufacture of pigments, paints, etc., from iron ore. 6d

## XIII.—TANNING, LEATHER, GLUE AND SIZE.

1885.

5233 H. E. Howe. Rendering leather used for soles of boots, etc., flexible, and proof against water or damp. 4d

7223 P. M. Justice.—Communicated by A. Sandron. Water proofing and preserving leather, etc. 6d

## XV.—SUGAR, STARCHES, GUMS, ETC.

1885.

500 F. B. Welch. Method of and apparatus for boiling sugar. 6d

603 C. D. Abel.—Communicated by M. M. Rotten. Production of sugar by treatment of saccharine solutions with the alkaline earths. 4d

2721 C. D. Abel.—Communicated by La Société Nouvelle de Refinerie de Sucre de St. Louis. Process for purification and decoloration of saccharine liquors, etc. 4d

11829 G. S. Baker. Machines for baking sugar, etc. 6d

12871 W. R. Lake.—Communicated by F. O. Matthieson. Bone black filters. 8d

12874 W. R. Lake (F. O. Matthieson). Process and apparatus for purification and decolorisation of sugar. 8d

12875 W. R. Lake (F. O. Matthieson and E. E. Quimby). Apparatus for decolorisation of saccharine or other liquor. 8d

12876 W. R. Lake (F. O. Matthieson). Apparatus for the filtration of sugar liquor. 8d

12877 W. R. Lake (F. O. Matthieson). Bone-black filters for filtering sugar liquor. 8d

12878 W. R. Lake (F. O. Matthieson). Apparatus for the decolorisation of sugar liquor. 8d

12879 W. R. Lake (E. E. Quimby). Apparatus for decolorising sugar liquor. 8d

## XVI.—BREWING, WINES AND SPIRITS.

1884.

16508 I. Levinstein. Apparatus for charging beer, etc., with gases, and discharging the liquid from its container. 6d

1885.

211 A. W. Gillman and S. Spence. Treatment of grain (cobs) used in brewing (distillation, etc.). 4d

12231 J. Dyer.—Communicated by — 4d

12232 J. Dyer.—Communicated by — 4d

12233 J. Dyer.—Communicated by — 4d

12234 J. Dyer.—Communicated by — 4d

12235 J. Dyer.—Communicated by — 4d

12236 J. Dyer.—Communicated by — 4d

12237 J. Dyer.—Communicated by — 4d

12238 J. Dyer.—Communicated by — 4d

12239 J. Dyer.—Communicated by — 4d

12240 J. Dyer.—Communicated by — 4d

12241 J. Dyer.—Communicated by — 4d

12242 J. Dyer.—Communicated by — 4d

12243 J. Dyer.—Communicated by — 4d

12244 J. Dyer.—Communicated by — 4d

12245 J. Dyer.—Communicated by — 4d

12246 J. Dyer.—Communicated by — 4d

12247 J. Dyer.—Communicated by — 4d

12248 J. Dyer.—Communicated by — 4d

12249 J. Dyer.—Communicated by — 4d

12250 J. Dyer.—Communicated by — 4d

12251 J. Dyer.—Communicated by — 4d

12252 J. Dyer.—Communicated by — 4d

## XVIII.—ELECTRO-CHEMISTRY.

1885.

157 G. F. Redfern.—Communicated by — Bernstein. Generation of electricity. 8d

- 1288 G. Forbes. Dynamo machines. 6d  
 1505 W. R. Lake—Communicated by Brevoort & Lewis.  
 Electric batteries. 6d  
 3728 W. R. Lake—Communicated by Brevoort & Roberts.  
 Electric batteries. 8d  
 6878 J. T. Armstrong. Electrical batteries, etc. 8d

REPRINT.

- 2951 of 1881 Electric machines. 8d

XIX.—PAPER, PASTEBOARD, Etc.

1881.

- 16186 A. Albutt—Communicated by A. Fellner. Preparing  
 a lye for the extraction of cellulose from wood. 6d  
 17083 J. Smith and P. W. Nivolle. Treating vegetable fibres  
 for the extraction of extraneous matters therefrom. 1d

1885.

- 367 J. Jameson. Preparation of safety paper, affording pro-  
 tection against erasure or alteration. 6d

XX.—FINE CHEMICALS, ALKALOIDS,  
 ESSENCES, AND EXTRACTS.

1881.

- 10636 E. C. and F. M. Allan. Manufacture of acetic acid  
 and apparatus therefor. 6d

1885.

- 157 L. Q. Brin and A. Brin. Separation and obtainment of  
 oxygen and nitrogen from atmospheric air. 8d

XXI.—EXPLOSIVES, MATCHES, Etc.

1885.

- 191 W. V. Wilson and J. Storey. Nitro-cellulose compound  
 and products manufactured therewith. 6d  
 552 H. S. Maxim. Manufacture of gunpowder, and cart-  
 ridges or charges containing same. 8d

REPRINTS.

- 500 of 1861. E. Dronke. Gunpowder. 6d  
 2062 of 1874 S. J. Mackie and others. Explosive compounds.  
 6d
